With regard to the cyanogen flame, he had nothing to withdraw from what he had said on a previous occasion, though he gladly congratulated Lewes on having now made a new and interesting observation. He had entirely failed to obtain evidence of carbon being separated in a cyanogen flame surrounded by burning hydrogen, and Lewes had not shown that it was separated. The use of nitric oxide (which would in its luminous result remind them of the behaviour of that gas towards carbon bisulphide) undoubtedly led to the separation of carbon, and supplied a piece of evidence which Lewes was now entitled to claim.

There was a calculation which was intended to give the theoretical illuminating value of ethane, ethylene, and acetylene respectively, on the supposition that in giving light after passing through the state of acetylene they were resolved into carbon and hydrogen, and this calculation gave results in tolerable agreement with the illuminating value of the gases as determined by the photometer. The calculation was, he thought, unintelligible from a scientific point of view, but, even if the principle were admitted, seemed not only incorrectly made, but capable of affording a set of numbers entirely at variance with practical measurements, just as easily as numbers in harmony with them. He thought some explanation of this was due from Lewes.

In reply in the discussion Prof. Lewes said that his views as to the structure of an ordinary gas flame were that it contained four parts, but that three of these, namely, the non-luminous inner zone, the luminous sheath, and the blue calyx were portions of the region in which no combustion, in the ordinary acceptance of the term, took place; whilst the outer mantle of the flame was the region of intense combustion, and is undoubtedly the hottest part of the flame. In a paper read in 1892, he had given a description of a gas flame, but, in criticising this, Smithells had evidently overlooked the fact that the portion of the paper following the description was devoted to an investigation as to the causes which led to the non-luminosity of hydrocarbon flames, which showed that the outer envelope must be the hottest portion of the flame, but it is also manifest that the outer side of this mantle must be rapidly cooled by admixture with air and products of combustion, so that the maximum temperature will be near the inner side of this region, and it

was the extreme outer portion of this zone which he had described in the words criticised by Smithells.

He thoroughly agreed in condemning any temperature measurements of those portions of the flame in which active combustion was going on, but still believed in the measurements obtained in the area of non-combustion.

The statement he had made was that 80 per cent. of the unsaturated hydrocarbons at the point just before luminosity commenced, consisted of acetylene.

If a mixture of 1·5 per cent. of acetylene and any gas which had a non-luminous flame was burnt, no luminosity would be generated, and no trace of acetylene would be detected at the top of the inner zone, it having been consumed before the temperature necessary for its decomposition was reached; but if 1·5 per cent. of acetylene were led into the top of the inner zone of a flame of coal-gas, from which the unsaturated hydrocarbons had been absorbed, then this addition would make the flame as luminous as if the unsaturated hydrocarbons had not been withdrawn.

Smithells concludes that because a platinum wire held in the outer sheath of a flame glows with the same incandescence as the carbon particles in the flame itself, therefore there is no need to assume any other source of heat than that given by the combustion going on in the flame walls.

It had been shown that metals at high temperatures reflect light, and he thought it quite possible that some of the apparent brightness of the platinum wire might be due to light reflected from the luminous veil in front of which the wire was placed.

Megass and Refuse Furnaces. W. P. Abell. Proc. Inst. Civil Eng. 1895, 123, 3.

See under XVI., page 210.

PATENTS.

Oil-enriched and Illuminating Water-Gas, and Apparatus therefor, Improved Process for Generating. B. H. Thwaite, London. Eng. Pat. 949, Jan. 15, 1895.

The invention consists substantially in employing two fuel-fed chambers A and B, in conjunction with a third fixing chamber filled with refractory material and built in such a way as to obtain the maximum amount of heating surface and heat-absorbing capacity in the space available. In the first

chamber the base of the fuel rests in a water-bath 5, the fuel being supported by hanging fire-bars 3, suspended from the inverted cone 4, whereby the steam and air can readily enter. The base of the fuel in the second chamber rests in the water-bath 5', the inverted cone at the base of the chamber dipping 8 to 12 ins. under the water, and so making a water-joint. These water-baths extend beyond the chambers

and enable the elinkers to be easily raked away from time to time without interfering with the gas production. The first chamber is connected at the top with the top of the second chamber by means of the conduit 9, and the bottom of the second chamber is connected with the fixing chamber C, by conduit 21. During the blow-up, primary air is admitted by the fire-bars 5, secondary and superheated air being admitted at 11, and, if desirable, in the conduit 21 at 13. When the heating is sufficient, the air supplies are cut off, steam is admitted at 5 and 11 (or a small current of air may be continued at 11 to aid in maintaining the heat), and oil is injected under pressure through finely perforated pipes either in the conduit 9 or into the upper layer of fuel in B. Special and detailed arrangements are made for feeding in the coal, injecting and regulating the oil, opening and closing the valves automatically, &c.—L. T. T.

Distilling, Cracking, or Gasifying Oils, Tars, or any Liquid Hydrocarbons, Improvement in Plant for. R. V. Horsfall, Skidwaite, Yorkshire. Eng. Pat. 2188, Jan. 31, 1895.

This consists in the use of sloping or horizontal retorts so arranged in separate chambers—or two or more in a chamber—and so connected with one another that the heating of the different retorts may be regulated to the temperatures required for the gasifying of the hydrocarbons therein. The upper retorts containing the fresh oils are least heated, the next lower, containing the residuals from the first and some of the condensation products from the mains, are more heated, and so on.—L. T. T.

Generating Gas, such as Acetylene, Improvements in Apparatus for. D. B. Morison. Eng. Pat. 2437, Feb. 4, 1895.

This apparatus consists of a portable lamp (constructed on the Kipp or Doeberlein system) for generating illuminating gas, such as acetylene, by the action of a liquid on a solid. It consists of an outer vessel containing water, and an inner vessel open at the bottom. The inner vessel is fitted with a perforated tray to carry the blocks of calcium carbide, and this tray is preferably supported on springs. Thus, as the carbide is decomposed and the lime falls through the perforations into the outer vessel and so raises the water-level, the springs raise the lightened tray, and thus keep the carbide at the right level.—L. T. T.

Retorts for the Manufacture of Gas and for other Purposes, Improvements in. J. J. Green and W. Oates, Claremount, Halifax, Yorkshire. Eng. Pat. 4282, Feb. 28, 1895.

The improvement consists in making a part or the whole of the surface of fixed fireclay retorts fluted or corrugated, thereby increasing the heating surface. The corrugations may be formed either within the retort, on the outer surface, or both together.—L. T. T.

The Injection or Ejection of Mineral Oils [for feeding Flare Lamps and Furnaces] or other Inflammable Fluids not Miscible with Water, and Apparatus therefor, An Improved Method of safely applying Compressed Air or Vapour under Pressure for. R. S. O. Bramwell, Grange-over-Sands. Eng. Pat. 4579, March 1, 1895.

This apparatus is for feeding inflammable fluids—which float upon water but do not mix with it—to flare lamps, furnaces, &c. It consists of two closed receptacles, one fixed inside the other. The outer vessel is partly filled with water, on top of which compressed air or steam can be admitted. The inner vessel, which contains the oil, has a port at its lower end communicating with the outer vessel, and a pipe leading from its upper end to the apparatus in which the oil is to be consumed. When pressure is applied to the upper surface of the water in the outer vessel by compressed air or steam, it is transmitted to the oil, which is thereby forced out.

Coke Ovens for the Manufacture of Metallurgic Coke, Improvements in Constructing and Working. W. Ure, Workington, and S. T. Croasdel, Whitehaven. Eng. Pat. 4760, March 6, 1895.

The coke ovens are provided with a lowering floor, which is also tilted at the proper moment to discharge the coke formed, the latter being afterwards quenched. The lowering and subsequent raising of the floor is performed by a lever operated by worm or other gearing. The charging-hopper is provided with two dampers, one above the other, the outer one being of iron and the inner one of firebrick or fireclay lump. An annular space is arranged around the oven, into which openings for the gaseous products enter, and from which they pass to the main flue. Tuyères are also provided to facilitate combustion.—R. S.

Artificial Fuel [Briquettes], Improvements relating to the Manufacture of. G. Hayeraft, Pontardulais. Eng. Pat. 4879, March 7, 1895.

Any suitable binding material, in the form of a film, is added to powdered coal for the formation of briquettes. In the plant designed for this purpose, the binding agent, as liquid or semi-liquid distillates of coal, is placed in two tanks, which are heated by a furnace to keep the contents in a liquid state. Into these tanks dip two rotating rolls, which deliver the binding agent to two other horizontal and parallel rolls, between which the powdered coal is fed. The mixture passes between a lower pair of rolls, and then falls, thoroughly incorporated together, out of the machine. The rollers are provided with scrapers for removing the mixture therefrom, and the first mixing pair has also an extra pair of scrapers for regulating the supply of the binding material.—R. S.

Burners for Incandescence Gas Light, Improvements in. R. Violet, Berlin. Eng. Pat. 5213, March 12, 1895.

Above the nozzle through which the gas issues from the supply-pipe and around which the air-apertures are arranged, is mounted a box or casing having a perforated bottom and a sieve top, while within it is a fan wheel which is carried by a pin so as to rotate rapidly as the air and gas pass upwards. Two or more such fans may be used, the wings of which are set alternately in opposite directions. By this arrangement the air and gas are thoroughly mixed, and also burn at a higher pressure than exists in the gas-pipe. The lower end of the mantle is secured against movement in a lateral direction, by a hinged or closed ring.—R. S.

Treatment of Coal-Dust to adapt it for Use as Fuel and for the Manufacture of Gas, Improvements in. A. McDougall, Birkdale. Eng. Pat. 6300, March 27, 1895.

Dry coal-dust is mixed with about 10 per cent. of tar, paraffin, or petroleum oil, whereby its heating and gas-yielding properties are improved.—R. S.

Flaming Lights used for Marine Purposes and the like, Improvements in. J. S. Comrie, London. Eng. Pat. 8720, May 2, 1895.

In that class of lights which are ignited by the action of water upon certain substances, calcium phosphide has hitherto been used.

The improvement claimed in this invention is the addition of calcium carbide. In some cases the two substances are simply mixed together, but it is preferred to enclose them in separate chambers, so arranged that the vapours mingle as they issue and burn together. The calcium phosphide provides the means of ignition, whilst the calcium carbide provides a vapour which when ignited yields a brilliant and steady light.—R. B. P.

Combustible Gas, Improvements in Processes and Apparatus for the Production of. H. H. Lake, London. From E. N. Dickerson, New York. Eng. Pat. 11,848, June 18, 1895.

The apparatus is for the automatic generation of combustible gases, especially acetylene gas, by the interaction of a solid and a liquid—especially of calcium carbide and water—for the supply of houses, &c. The carbide is contained in the upper half of an hour-glass shaped vessel, the

lower, open end of which stands in a large tank of water. Just below the most constricted part of the vessel is placed a grate on which the blocks of carbide rest. The water in the outer tank stands at such a level as to enable it to rise in the carbide vessel to a short distance above the grate. The lime formed during the decomposition of the carbide falls through the grate into a removable tray. Special valves and systems of pipes are arranged to minimise the escape of acetylene, and the whole apparatus is enclosed in a chamber which may be efficiently ventilated, and also both the chamber and the water may, if desirable, be warmed.

—L. T. T.

Combustible Gas for Illuminating Purposes, An Improved Method and Apparatus for Supplying. H. H. Lake, London. From E. N. Dickerson, New York. Eng. Pat. 11,848v, June 18, 1895.

THE patentee claims the discovery that acetylene gas can be liquefied, under suitable conditions, at reasonable pressures, and subsequently utilised for illuminating purposes. The invention consists in using cylinders of liquid acetylene fitted with suitable reducing valves, governors, &c. The patentee burns the gas alone, or preferably with a certain admixture of air effected in a mixing chamber.

—L. T. T.

Enriching Illuminating Gas, Improvements in Apparatus for. W. Ewing, Hamilton, Lanarkshire, and J. Meikle, Glasgow. Eng. Pat. 19,916, Oct. 23, 1895.

THIS consists of a constant-level carburetter, consisting of two parts, the one being a closed receiver containing the main body of the carburetting liquid, the only outlet of which terminates near the base of the lower or carburetting vessel. In this way a constant level of the carburetting liquid is maintained, and by means of a diaphragm over the surface of this liquid and fitted with circular plates dipping into the liquid, the gas to be carburetted is made to take a circuitous course over the surface of and finally through the carburetting liquid, and is thus more evenly and efficiently carburetted than in the usual carburetters. The upper storage vessel is fitted with taps, screw-joints, &c., so that it may be detached and refilled.—L. T. T.

Petroleum, An Improved Method of Increasing the Lighting Power of. N. Baroa, Budapesth. Eng. Pat. 21,927, Nov. 18, 1895.

THE addition of paraffin to petroleum increases its lighting power, but increases the rate of consumption at the same time.

According to the present invention, this objection is obviated by also adding spermaceti.

Two parts of the purest hard white paraffin may be used to one part of pure hard spermaceti, and 0.3 gram. of the mixture will last for four days in a lamp holding half a litre, the petroleum being replenished from time to time as required. The addition of this mixture, it is stated, also does away with the objectionable smell of certain petroleum.—R. B. P.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Petroleum, Elementary Composition of. C. Engler and L. Jezioranski. Ber. 1895, 28, 2501—2505.

THE attention of investigators has hitherto been mainly directed to the fractions boiling between 150° and 160°, or less frequently 200°, whereas the composition of the higher boiling fractions has been but little studied, and it has been taken for granted that, apart from the small quantities of acetylene, benzene, naphthalene, &c., isolated from the latter, their nature corresponds with that of the light fractions. This is, however, not the case, the ratio of carbon to hydrogen (and therefore the proportion of unsaturated hydrocarbons) increasing with the boiling point, till in the higher fractions the unsaturated compounds greatly predominate. This is shown by their behaviour

towards sulphuric acid, and by the comparatively small amount of solid paraffin that separates out.

The analytical tables given show a larger percentage of carbon than is present in bodies of the methane series with boiling points corresponding to those given; this percentage also exceeds that of the ethylene series, thus leading to the conclusion that whilst the lighter fractions consist chiefly of saturated hydrocarbons, the fractions above 200° contain a predominating proportion of unsaturated bodies.

The authors' attention was first called to this matter by the formation of water in the preparation of petroleum by distilling train oil under pressure. If petroleum has been formed from fats or fatty acids, the general formula for crude oil (C_nH_{2n} rather than C_nH_{2n+2}) indicates that a good deal of water must have been driven off during the process of conversion.—C. S.

PATENT.

Distilling, Cracking, or Gasifying Oils, Tars, or any Liquid Hydrocarbons, Improvements in Plant for. R. V. Horsfall, Skithwaite, Yorkshire. Eng. Pat. 2188, Jan. 31, 1895.

See under II., page 190.

Retort for Distilling Heavy Bodies in General, and Particularly Gum and Resin. V. J. Kuess, Paris. Eng. Pat. 4882, March 7, 1895.

THIS invention renders it possible to extract spirits of turpentine and oil of resin in one retort, and to introduce steam into the same without effervescence, and thus obtain results in a shorter time, whilst the unpleasant taste and disagreeable odour, which at present accompany hydrocarbons of the turpentine series, are eliminated. The distilling apparatus consists of a jacketed still, heated by means of superheated steam. The top of the still is provided with the ordinary head and neck; the latter, instead of being directly connected with the condenser, is arranged to enter a short distance within a tube of larger diameter, communicating with the condenser in such a manner as to form a hollow annular ring, through which superheated steam passes. A pipe is led through the head and descends vertically nearly to the bottom of the inner bath, where it branches off in different directions, and is joined to and carries an annular pipe, perforated with small holes and concentric with it. This pipe carries two perforated discs, preferably of aluminium, which are connected to the electrodes of a dynamo. If desired, an electrical superheater may be placed at the bottom of the inner bath for the purpose of simplifying the distillation and also improving the quality of the products. The gum or other substances having been introduced into the inner bath, steam is admitted into the pipes and an electrical current passed through the wires. Electrolysis is set up and the gum in the bath is decomposed. The distillation proceeding, the steam, which issues with some force into the neck of the retort, surrounds the vapour and steam issuing from the inner bath, and carries it along with it to the condenser.—D. B.

Wood, Treatment of, with a View to Preserving and Colouring the Same. R. Aitken, London. Eng. Pat. 2710, Feb. 7, 1895.

See under IX., page 199.

IV.—COLOURING MATTERS AND DYES.

Fisetin, Constitution of. St. von Kostanecki and J. Tambor. Ber. 1895, 28, 2302—2309.

ALL the three dyestuffs, chrysin, quercetin, and fisetin, are derivatives of β -phenyl-pheno- γ -pyrone—

chrysin being—

quercetin—

and fisetin—

The products of decomposition by fusion with potash of fisetin are resorcinol, protocatechuic acid, and glycollic acid.

There are two formulae possible for the resorcinol nucleus of fisetin. The accuracy of that ascribed as above is proved by the ready convertibility of fisetin into its tetra-alkyl derivatives, compounds containing hydroxyl-groups in the resorcinol nucleus in the other position possible, namely, ortho to the carbonyl-group, as chrysin and quercetin, for instance, not being susceptible of complete etherification.

Moreover, the diethylfisetol ether which, as Herzig has shown, is produced along with diethylprotocatechuic acid when tetra-ethylfisetin is boiled with alcoholic potash, is found to have the constitution—

—E. B.

Triphenyl Carbinol, New Methods of Formation of.

Hg. Frey. Ber. 28, 2514—2521.

ATTEMPTS to introduce the CO group into an organic radicle by decomposing ethyl oxalate with sodium in presence of an organic halogen compound, led to the discovery that ethyl oxalate when treated with sodium in ether, is decomposed into carbonic oxide and ethyl carbonate at ordinary temperatures. By acting on a mixture of ethyl oxalate and bromobenzene in ether with sodium, carbonic oxide and hydrogen are given off, and in place of the benzophenone expected, triphenylcarbinol, together with a not inconsiderable quantity of benzoic acid, is produced. Benzaldehyde appears to be formed as an intermediate product, and both this substance and benzophenone, when treated together with bromobenzene in dry ether with sodium, yield triphenyl carbinol, and in the case of benzophenone the yield is almost quantitative. It was not, however, possible to obtain pararosaniline by the action of sodium on a mixture of oxalic ether and *p*-bromaniline, although two different stable nitrogen compounds of high melting point are produced. Experimenting in the aliphatic series, the author attempted to prepare trimethyl carbinol by the action of sodium on a mixture of acetone and methyl iodide. Although a small quantity is formed, the principal product is isopropyl alcohol.—T. A. L.

Naphthazarin from δ-Tetranitronaphthalene, Formation of.

W. Will. Ber. 1895, 28, 2231—2235.

δ-TETRANITRONAPHTHALENE (1:2:1':1') (Ber. 28, 369) yields, on reduction with tin and hydrochloric acid, the tin double salt of the corresponding tetramide compound. This is decomposed by an excess of sodium hydroxide with separation of crystals of the base, which have a bronze reflex. The base is converted by the addition of hydrochloric acid in alcoholic solution into the hydrochloride of amidodimido-naphthol, which separates as a granular blue precipitate. From this, naphthazarin is obtained by boiling with dilute hydrochloric acid, the solution changing in colour from blue to red, and when sufficiently concentrated, depositing, on

cooling, naphthazarin in red-brown flocks, the yield amounting to 50—60 per cent. of the theoretical. The formation of naphthazarin appears to be assisted by the addition to the acidified solution of a small quantity of ferric chloride.

—E. B.

Indulines to Safranines, Relations of. O. Fischer and E. Hepp. Ber. 1895, 28, 2283—2289.

THE authors, as a result of further investigation of the safranines and indulines, conclude that these colouring matters belong to the same group.

The close connection of these two series of colouring matters is exhibited by the formation of anilido-aposafranine (formerly named benzene-indone; Ann. 266, 254) from aposafranine—

by heating with aniline and aniline hydrochloride.

In accordance with this relation, the formula of the anilido-compound must be expressed as $C_{24}H_{17}N_3O$.

Anilido-aposafranine gives, on heating with 7.5 per cent. sulphuric acid, hydroxyaposafranine (Nietzki and Otto's safranin), a compound which may also be directly obtained from aposafranine by boiling with alcoholic potash.

Aposafranine is reproduced from anilido-aposafranine when the latter is treated in 60 per cent. boiling acetic acid with zinc dust, and the leuco-compound formed is oxidised. In a similar manner, the simplest induline, anilido-aposafranine, prepared by Kehrman (this Journal, 1895, 858), is converted into aposafranine (this Journal, 1894, 30).

Phenylinduline is derived from anilido-aposafranine by the substitution of a phenylimido-group for the oxygen atom, and must therefore have the formula, $C_{30}H_{23}N_3$, instead of that formerly assigned to it, namely, $C_{24}H_{17}N_3$. Its formation from azophenine is explained on the assumption that two atoms of hydrogen are withdrawn from this compound, thus:—

further condensation in the same way giving diphenyl-fluorindine—

The indulines must, therefore, be regarded as anilido-safranines. The mauveines (phenylsafranines), indazines, rosindulines, naphthyl red and blue, Magdala red and its homologues, phenosafranine and its homologues, and the indulines thus, all belong to the same group.

Two of the objections made to the grouping of the safranines with the indulines—namely, that phenosafranine contains a hydroxyl-group or combined water, and that the safranines in certain of their properties resemble ammonium compounds—are based on misconceptions. Hydroxy-aposafranine contains only one hydroxyl-group, and phenosafranine at 100°, if not at the ordinary temperature, is anhydrous. Aposafranine was not obtained by the authors free from water (less than $\frac{1}{2}$ mol.), but its benzoyl derivative was obtained entirely free. Further, the safranin bases are precipitated from solutions of their salts by alkali

hydroxides, free from carbonates, and are extractable by ether, thus differing from ammonium derivatives of closed chain compounds.—E. B.

Azo Colouring Matters, Observations on. E. Bamberger and F. Meimberg. Ber. 28, 1887—1897.

BAMBERGER brings forward further evidence in support of the views, as already stated (Ber. 28, 837), that both normal and isodiazobenzene compounds, when combined, yield identical azo compounds, and finds that this is also the case with the products from ethyl- and methylaniline when combined with normal or with iso-*p*-nitrodiazobenzene. Hantzsch's results as to the constitution of the isomeric *p*-nitrophenyl-azo- α -naphthols obtained by the action of *p*-nitrodiazobenzene hydrate with α -naphthol are confirmed by the authors, who also agree that the two compounds are *p*- and *o*-derivatives of naphthalene, and they adduce further evidence to show that, even with a free para position, certain phenols are substituted in the position ortho to the hydroxyl. Thus from diazotised *o*-nitraniline and α -naphthol they obtain *o*-nitrophenyl-*p*-azo- α -naphthol (1.4)OH. $C_{10}H_7.N_2.C_6H_4.NO_2(1.2)$, which crystallises in bronzy dark-red needles, melts at 244° — 245° C., and dissolves easily in hot xylene and amyl alcohol. On reduction it gives *o*-phenylene diamine and (1.4)-amidonaphthol, the latter when oxidised yielding α -naphthoquinone. The isomeric compound *o*-nitrophenyl-*o*-azo- α -naphthol (1.2)OH. $C_{10}H_7.N_2.C_6H_4.NO_2(1.2)$, is produced, together with the para compound, by the action of α -naphthol on *o*-nitrodiazobenzene methyl ether (obtained from the silver salt of *o*-nitro-isodiazobenzene and methyl iodide). On reduction and oxidation with ferric chloride no α -naphthoquinone is obtained, the reduction product being 2.1-amidonaphthol. Both the ortho- and the para-compounds are soluble in alkalis, but whilst the solution of the former is almost completely precipitated by water, that of the latter requires the addition of an acid, when it is precipitated in yellow flocks. The authors confirm Bamberger's previous statement that dialkylated *o*-toluidines will combine with diazo-compounds to form colouring matters, and describe the preparation of *p*-nitrophenyl-azo-diethyl-*o*-toluidine from diazotised *p*-nitraniline and diethyl-*o*-toluidine in presence of sodium acetate. On the other hand, no dyestuff is formed from *p*-nitro-isodiazobenzene and diethyl- or dimethyl-*o*-toluidine.

Experiments have also been made as to the replacement of one component in an azo dyestuff by another, a reaction which can be brought about in certain cases. Thus, for example, when α -naphthylamine dissolved in acetic acid is added to *p*-nitrophenylazomethylaniline and the mixture is allowed to stand, there results Meldola's *p*-nitrophenyl-azo- α -naphthylamine, and in a similar manner methyl- and ethyl-aniline can be replaced by α - and β -naphthol in the compounds resulting from the combination of these substances with *p*-nitrodiazobenzene.

In conclusion the authors call attention to the formation of certain disazo colouring matters which have been overlooked in the preparation of some azo dyestuffs. When diazobenzene chloride is combined with alkaline α -naphthol, 33 per cent. of the product consists of bis-phenylazo- α -naphthol, $C_{10}H_7(OH)(N_2.C_6H_5)_2$, which crystallises in bronzy greenish-black matted needles melting at 190° — 191° C. (cf. Krohn, Ber. 21, 3240; this Journal, 1889, 116). Bis-*p*-tolylazo- α -naphthol, $(OH)(C_{10}H_7(N_2.C_6H_4.CH_3)_2)$, crystallising in dark violet-brown matted needles melting at 205° — 206° C., insoluble in alkalis, is formed, together with *p*-tolyl-azo- α -naphthol (m.p. 209° — 210° C.), by the action of diazotised *p*-toluidine on α -naphthol. Bis-*p*-bromophenyl-azo- α -naphthol, $HO.C_{10}H_7(N_2.C_6H_4.Br)_2$, from diazotised *p*-bromaniline and α -naphthol in an alkaline solution, crystallises in green needles melting at 233° — 235° C., is formed together with *p*-bromophenyl-azo- α -naphthol which melts at 237° — 238° C., and not, as Margary (Gazz. Chim. Ital. 14, 271) states, at 185° or 195° — 196° C. The bisazo compound is very sparingly soluble in warm dilute alkali, but dissolves easily in benzene or toluene, whilst concentrated sulphuric acid dissolves it with a greyish-green colour.—T. A. L.

Nitranilines, Preparation of the Three. E. Bruns. Ber. 28, 1954—1955.

THE method consists in nitrating aniline in presence of sulphuric acid and subsequently separating the three isomers by means of their different basicities. Aniline dissolved in 6—8 times its weight of concentrated sulphuric acid is nitrated with the theoretical amount of nitric acid mixed with an equal volume of sulphuric acid. The operation must be performed below 9° C., and after the nitration is complete, the melt is poured on to ice, and ice-water is added as long as a precipitate of *o*-nitraniline is produced. After one crystallisation from alcohol the product has the correct melting-point. The filtrate from the *o*-nitraniline is neutralised with powdered sodium carbonate, any tar which separates being first filtered off. On further neutralisation, *p*-nitraniline separates as a yellowish-brown precipitate, whilst finally, *m*-nitraniline is precipitated as a pure yellow precipitate. The change from brown to yellow is said to be very sharp, and after one crystallisation the nitranilines are pure, having the melting-points 147° and 110° C. respectively. With regard to the yields, 10—15 per cent. of *o*-nitraniline is obtained, whilst about 45—50 per cent. of *m*- and *p*-nitraniline are formed in approximately equal quantities.—T. A. L.

Allofluorescein. B. Pawlewski. Ber. 28, 2360—2362.

WHEN phthalyl chloride and resorcinol are heated on the water-bath, either alone or in solution, a yellowish amorphous mass is obtained, which fluoresces strongly in an alkaline solution. The melt is purified by treatment with acetic anhydride for several hours at 150° — 170° C., and after evaporating the liquid, the residue is repeatedly extracted with alcohol and acetic acid, a slightly yellowish amorphous substance being obtained. The pure substance is white, melts at 140° C., fluoresces strongly in an alkaline solution, and is nearly insoluble in all solvents. It has the formula—

and is termed allofluorescein. The author in conclusion compares this modification with ordinary fluorescein, from which it would appear that although in solutions of equal strengths allofluorescein shows a greener and denser fluorescence, when diluted it disappears sooner, and solutions containing 0.000001866 per cent. are colourless, whereas ordinary fluorescein of this strength shows a distinct fluorescence on a dark background.—T. A. L.

Indigotin, The Red Isomeride of, and some Derivatives of Isatin. E. Schunck and L. Marchlewski. Ber. 28, 2325—2331.

THE authors have already shown (Ber. 28, 539) that the three compounds described as red isomerides of indigotin are identical, and this identity is further proved by the fact that when treated with zinc dust and acetic anhydride in presence of fused sodium acetate they all yield acetylindilencin—

which crystallises in pink shining needles melting at 204° C., and by treatment with alkalis can be converted into indilencin.

Dimethylindirubin, prepared by reducing in a similar manner *p*-methyl isatin chloride, has probably the constitutional formula—

It crystallises from aniline in chocolate-brown needles, and has similar properties to indirubin.

Isatin-methyl-phenylhydrazine, obtained by boiling an alcoholic solution of isatin with methyl-phenylhydrazine, together with some acetic acid, is a true hydrazone, and crystallises from alcohol in orange needles melting at 172° — 173° C.

Isatin-β-naphthylhydrazine, crystallising in dark yellow needles melting at 231° C., is obtained by boiling an alcoholic solution of isatin with β-naphthylhydrazine hydrochloride in presence of sodium acetate.

By acting on isatin with *o*-phenylene diamine, isatohydrophenazine, C₁₁H₇N₃, is obtained, which crystallises from alcohol or sublimes in yellow needles melting at 285°–287° C. The substance is stable to acids and alkalis, and gives an acetyl compound melting at 202° C. When *o*-phenylene diamine is condensed with *m*-chlorisatin, *m*-chlor-isatohydrophenazine—

is obtained.—T. A. L.

Paranitro Compounds, Electrolytic Reduction of, in Sulphuric Acid Solution. A. A. Noyes and J. T. Dorrance. J. Amer. Chem. Soc. 1895, 17, 855–859.

THE authors have investigated the action of electrolytic hydrogen on paranitraniline, paranitrophenol, and parachloronitrobenzene. All the paranitro compounds which have now been investigated are included in the following list, each with its reaction product:—

In the case of paranitrobenzoic acid and parachloronitrobenzene, the residue para to the nitro group is in each case driven out; this action may be characteristic of nitro-compounds with negative para groups, but further investigation is necessary to warrant any generalisation on this point. In only one case (that of nitrotoluidine) does the oxygen show any tendency to migrate to any other than the para-position. The experiments were made by dissolving 20 to 30 grms. of the substance in 2½ to 3 times that weight of strong sulphuric acid, and electrolysing with a large platinum electrode in a vessel containing a porous cup with sulphuric acid and a small platinum electrode. A current of from 1 to 2 ampères was employed for from 40 to 50 hours.—W. G. M.

Indigo, Formation of, by the Action of Sunlight. Engler and Dorant. Ber. 28, 2497–2501.

BENZYLIDENE-ortho-nitro-acetophenone—

is formed by the condensation of ortho-nitro-acetophenone and benzyl-aldehyde in alcoholic solution. When recrystallised from alcohol or ether it forms colourless long silky needles. When these crystals are exposed to sunlight for an hour or so, they begin to darken, and finally become dark blue; this is due to the formation of indigo-blue, which is caused by inter-molecular oxidation. No action takes place in the dark, very little in red light, more in yellow and green, and most in blue light.—A. L. S.

Luteol (Hydroxychlorodiphenylquinoxalin), New Indicator. W. Antenrieth. Archiv. d. Pharm. 233, 43.

PATENTS.

Dyestuffs [Azine Reds and Blues], the Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4880, March 7, 1895.

THE symmetrical and mixed dialkylated 1,3-naphthylene diamines and their sulphonic acids, obtained according to Eng. Pats. 8898, 16,780, and 19,623 of 1893 (this Journal, 1894, 511, 801, and 912), can be converted into hitherto unknown mordant azine dyestuffs. The process consists in heating these products with nitroso or azo compounds of the benzene or naphthalene series—such, for example, as those

derived from *o*-hydroxy-carboxylic acids (salicylic acid, hydroxynaphthoic acid, &c.) and from *o*- or peri-dihydroxy compounds of the benzene or naphthalene series. If necessary, the resulting azine compounds may be sulphonated to render them soluble. A mixture of 7.8 kilos. of 1,3,1'-diphenyl-naphthylene diamine sulphonic acid, 8 kilos. of benzene-azo-dihydroxynaphthalene [4.1.1'], 2.7 kilos. of sodium acetate, and 20 kilos. of glacial acetic acid, is heated for six hours, until the solution is blue, and when cold it is poured into alcohol. After filtering and washing, the monosulphonic acid obtained is preferably converted into a polysulphonic acid by sulphonation with fuming sulphuric acid (containing 25 per cent. SO₃) at 50° C. On pouring the melt into water, the sulphonic acid separates out, and after conversion into its sodium salt, is soluble in hot water. It gives blue shades on chrome-mordanted wool, fast to alkalis and acids. The above is a typical example, but any other processes for the production of azines may be employed for the purposes of this invention.—T. A. L.

Hydroxyanthraquinones [Anthracene Dyestuffs], The Manufacture or Production of Derivatives of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4951, March 8, 1895.

THE derivatives referred to are obtained by the action of primary aromatic amines and diamines (aniline, *o*- and *p*-toluidine, xylydine, *α*- and *β*-naphthylamine, *m*- and *p*-phenylene diamine, *m*-tolylene diamine, benzidine, and *p*-diamidodiphenylmethane) on hydroxyanthraquinones, such as quinizarin, purpurin, hydroxyanthra- and flavo-purpurin, anthrachrysone, alizarin bordeaux, pentacyanine and hexacyanine, and hexahydroxyanthraquinone. The condensation is carried out in presence of a condensing agent, such as boric, hydrochloric, hydrobromic, hydrofluoric, sulphuric, phosphoric, acetic, or benzoic acid, or zinc chloride. The resulting disubstituted products can, after sulphonation, be employed as valuable dyestuffs. A mixture of 10 kilos. of dry Alizarin blue (dihydroxy-anthraquinone quinoline), 200 kilos. of aniline, and 10 kilos. of crystallised boric acid, is heated for three hours to 130° C. After removing the excess of aniline and boric acid, the residue, after drying, is dissolved in 10 times its weight of sulphuric acid, and this solution is poured into a large quantity of water. The precipitated dyestuff, after filtering off, when boiled for a certain time with dilute acids or alkalis, is decomposed into Alizarin blue and aniline. It gives bluish-green shades on chromed wool. The production of a sulphonic acid by direct condensation is illustrated in the following example:—10 kilos. of quinizarin sulphonic acid, 100 kilos. of *p*-toluidine, and 10 kilos. of boric acid are heated at 130° C., until the greenish colour of the melt no longer increases. After steaming, to remove the excess of *p*-toluidine, the residue, which is the sulphonated dyestuff, is crystallised from dilute hydrochloric acid. It dissolves readily in pure water, and gives green shades on unmordanted and on chromed wool. In some cases no condensing agent is required, but under these circumstances a higher temperature must generally be employed. Thus, by cohobating 10 kilos. of purpurin with 100 kilos. of *p*-toluidine until the purpurin has disappeared, the new product formed can be isolated in the usual manner and employed for the production of dyestuffs.—T. A. L.

Alpha₁ Beta₂-dihydroxynaphthalene, The Manufacture or Production of, a New Alpha₁ Beta₂-dihydroxynaphthalene Sulphonic Acid, and of Colouring Matters derived from Alpha₁ Beta₂-dihydroxynaphthalene Sulphonic Acids. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 1962, March 8, 1895.

THE dihydroxynaphthalene disulphonic acid Y of Eng. Pat. 23,074 of 1893 (this Journal, 1894, 1191), when heated with water or dilute mineral acids at high temperatures, loses one sulphonic acid group and is converted into naphtharesoreinol sulphonic acid (1,3,2'-dihydroxynaphthalene sulphonic acid). When this acid is heated at still higher temperatures under the same conditions, it yields naphtharesoreinol (1,3-dihydroxynaphthalene), melting at

124° C. (Eng. Pat. 3580 of 1895; this Journal, 1896, 110). The new sulphonic acid will combine with tetrazo compounds, and the product derived from dianisidine and 1,3,2'-dihydroxynaphthalene sulphonic acid dyes reddish-violet shades on unmordanted cotton, fast to light, from a bath alkaline with potassium carbonate.—T. A. L.

Basic Azine Dyestuffs, The Manufacture or Production of, and of New Derivatives thereof. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5042, March 9, 1895.

According to Eng. Pat. 16,815 of 1892 (this Journal, 1893, 755) a process was described for producing basic colouring matters by condensing with amido azo compounds, alkyl-*m*-tolylene diamines ($\text{NH}_2 : \text{CH}_3 : \text{NHR} = 1 : 2 : 5$). Similar colouring matters and analogues thereof—for instance, those derived from benzyl-*m*-tolylene diamine—can now be obtained by any of the known methods for the production of similar azine dyestuffs. The various methods are: (1.) Condensing methyl, ethyl, or benzyl tolylene diamine with the nitroso-derivatives of secondary or tertiary aromatic amines or substituted amines. (2.) Joint oxidation of any of the preceding diamines with the *p*-diamines obtained by reducing the afore-mentioned nitroso-derivatives. (3.) Condensing primary, secondary, or tertiary aromatic amido compounds with azo compounds derived from alkyl-*m*-tolylene diamines and a diazotised amine. (4.) Joint oxidation of the alkyltriamido toluenes, obtained by reduction of the azo compounds in (3), together with primary, secondary, and tertiary amines. The dyestuffs produced according to these methods are similar to the safranines, from which they differ in containing a fatty radicle attached to an azine nitrogen, whereas in the safranines the substituting group is a phenyl or tolyl radicle. The following example gives the quantities employed:—A mixture of 28 kilos. of nitrosomethyl-*o*-toluidine hydrochloride, 15 kilos. of ethyl-*m*-tolylene diamine, and 100 to 200 kilos. of alcohol is heated on a water-bath until a clear red solution is obtained, when the whole is poured into water made slightly alkaline with ammonia, and filtered. After making acid with hydrochloric acid, the dyestuff is precipitated with salt, and after filter-pressing, is dried. It has the following constitution:—

and gives yellowish-red shades on tanned cotton. A further colouring matter can be produced from it by dissolving 3.1 kilos. in water and diazotising the solution with 3–4 kilos. of hydrochloric acid and 0.7 kilo. of sodium nitrite at a temperature below 5° C. When the solution has become a clear blue, 1.5 kilo. of β -naphthol in the calculated amount of soda-lye is added, and subsequently dilute soda-lye or sodium carbonate is stirred in until, on salting out and filtering a sample, a neutral filtrate is obtained. The dyestuff is then salted out, filter-pressed, and dried. It can be purified by crystallisation, and gives blue shades on tanned cotton.—T. A. L.

Dyestuffs [Safranines], The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 6328, March 27, 1895.

THESE dyestuffs are obtained by condensing the nitroso-compounds of alkyl-*o*-toluidines with two molecular proportions of a primary aromatic amine having a free para position, or else with one molecular proportion of any primary monamine and one molecular proportion of a monamine unsubstituted in the para position. The following is a typical example of the method employed:—11 kilos. of *p*-toluidine, and 12 kilos. of methyl-*o*-toluidine are dissolved in 100 kilos. of alcohol, 18.6 kilos. of nitro-*o*-methyl-*o*-toluidine hydrochloride being subsequently added to the resulting solution, heated on a water-bath. The reaction soon commences, forming a deep red-coloured

solution, and after heating about an hour, the liquid is acidulated with acetic acid, and the oxidation is completed by gradually adding 20 kilos. of potassium bichromate as a 5 per cent. solution. After distilling off the alcohol, the residue is acidulated with hydrochloric acid, and extracted with hot water, the dyestuff being finally salted out from the filtrate. It is identical with that previously obtained by the patentees from equimolecular proportions of *p*-amidomethyl-*o*-toluidine, methyl-*o*-toluidine, and *p*-toluidine. (See also Eng. Pat. 2900 of 1895; this Journal, 1896, 109.)—T. A. L.

Azo Dyes of the Benzidine and Analogous Series, The Manufacture and Production of. J. Y. Johnson, London. From "The Badische Anilin and Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 6697, April 1, 1895.

THE method hitherto employed for the production of the benzidine and homologous series of dyestuffs has consisted in the combination of the tetrazotised bases with amines and phenols and their derivatives. According to the present invention, these colouring matters can be obtained by oxidising certain azo dyestuffs, according to the following scheme:—

where B is an aniline radicle or other amido compound with a free para position, and X is an azo-dye component. The production of Congo red is carried out as follows:—About 35 kilos. of the azo dye, aniline-azo-naphthionic acid, are dissolved in 300 kilos. of 92 per cent. sulphuric acid, and oxidised with about 20 kilos. of 50 per cent. manganese peroxide at a temperature not exceeding 20°–25° C. When no further formation of disazo dyestuff is observable, the melt is poured on to ice, preferably in presence of sulphurous acid. After filtering and washing, the acid is converted into the sodium salt and purified either by means of the calcium salt or else by redissolving and again salting out. Ammonium persulphate or lead peroxide may also be used as oxidising agents.—T. A. L.

Extracting the Colouring Matter from Dyewoods, Process and Apparatus for. F. E. Mafat, Paris, France. Eng. Pat. 6967, April 4, 1895.

THE apparatus, of which a drawing is given, consists of a series of air-tight vessels connected by suitable communicating pipes and fitted with steam coils and exhaust. After charging each vessel, which has the shape of a truncated cone, with fragments of the dyewood, the first vessel is exhausted of air, and water, kept hot by the steam coil, is admitted, which extracts the dyewood therein. The second vessel is then exhausted, and the liquor from the first admitted to it, fresh water being drawn into the first vessel. The liquor in this manner passes through the series of vessels (generally 5), and the spent wood having been discharged from the first vessel, and this recharged with fresh, the concentrated liquor is drawn on to it and then discharged. It is claimed that by this means a very complete exhaustion of the dyewood is effected.—T. A. L.

Orange Colouring Matters by Electro-Chemical Process, Manufacture of. O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 22,482, Nov. 25, 1895.

By reducing the yellow alkaline condensation products of *p*-nitrotoluene sulphonic acid in an alkaline solution by means of the electric current, the yellow colouring matters are converted into orange dyestuffs. A mercury cathode is preferably employed, as the reduction then proceeds at a lower temperature. The best strength of current is 5–15 ampères per square decimetre of cathode area. About 10 kilos. of *p*-nitrotoluene sodium sulphonate are condensed in the usual manner in an aqueous solution with 30 kilos. of soda lye of 30° B. After dilution with 70 litres of water, the whole is reduced at 45° C. in an electrolytic cell with a mercury cathode until a sample spotted on paper shows a red spot free from yellow. The solution is then neutralised and the dyestuff salted out. After filtering and drying, it

forms a dark brown powder easily soluble in water with a yellowish-red colour, and in concentrated sulphuric acid with a dark violet-blue colour. It dyes unmordanted cotton orange from a neutral or alkaline bath, fast to air, chlorine, and acids.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

PATENTS.

Oiling or Waxing of Animal Fibres or Yarns, and Mixed Animal and Vegetable Fibres or Yarns, and Fabrics made from such Materials, Improvements relating to. R. Aitken, London. Eng. Pat. 2711, Feb. 7, 1895.

The materials (for instance, rags destined for use in the manufacture of shoddy) are placed inside a cylinder and impregnated with the oil, which it is desired to apply to them, in solution in an appropriate volatile solvent. The excess of the solution is withdrawn, and the solvent retained by the materials is expelled by heating, and condensed for use again.—E. B.

Stalk Fibres, An Improved Method of Degumming or Separating the Filaments of. K. T. Sutherland and G. Esdaile, Manchester. Eng. Pat. 3011, Feb. 12, 1895.

The degumming is effected by means of a hot, "neutral" solution of resin soap, prepared by dissolving colophony-resin in caustic soda, followed by treatment with a dilute solution of alkali.—E. B.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Wool, Lactic Acid for Mordanting. E. Hoffmann. *Färber Zeit.* 7, 65. (See also this Journal, 1882, 363; 1883, 176; 1885, 116; 1886, 677; 1891, 362. *J. Soc. Dyers and Col.* 1895, 98.)

For most alizarin colours lactic acid is to be preferred for wool-chroming to tartar, and particularly to oxalic acid.

Alizarin red, alizarin blue, anthracene blue, and anthracene brown yield on chrome and lactic acid mordant darker shades than on chrome and tartar, the difference being still more pronounced when compared with dyeings on chrome and oxalic acid. 14 per cent. of Alizarin blue SRW or WX gave with lactic acid the same depth of shade as 15 per cent. with tartar, and 16.5 per cent. with oxalic acid. Wool chromed with the aid of lactic acid is darker, and the exhausted bath of a lighter colour than with tartar, and more so than with oxalic acid. From this the author concludes

that with lactic acid more chrome is fixed on the fibre. Fuller and brighter shades are obtained both with alizarin and dyewoods, and less of colouring matter is required. The softness of the fibre is equal to that of fibre mordanted with tartar, whilst oxalic acid imparts harshness to the wool.—I. S.

Slubbing Dyeing, Suitable Dyes and New Apparatus for. J. Berger. *Färber Zeit.* 1895, 7, 81—82.

Such colouring matters only should be selected which, besides possessing the necessary fastness, penetrate well and dye evenly. Only few of the fast dyes possess these qualities. The chief of these are:—Alizarin reds, Milling orange, and Milling yellow (Dahl), Alizarin greens G and B (Dahl), all brands of Anthracene blue, Brilliant alizarin blues G and R, Brilliant alizarin cyanines G and 3 G, Alizarin cyanine R extra, Gallen, Galloeyanine (Duraud), Wool violet (Bayer), Diamond brown (Bayer), Chrome brown (Hoechst and Bayer), Diamond black (Bayer, single-bath method), Alizarin black (Badische), and Alizarin cyanine black (Bayer). Anthracene brown, though indispensable for brown shades, is not to be classed among these; but with care may yield good results.

Two modifications of a new apparatus are described. It consists of a wooden tub, about 3 ch. m. capacity, to the bottom of which is fitted from the inside a hollow copper plate with five round sleeves 10 cm. high. In the centre of this plate is an injector of special construction to convey either hot or cold liquids. The injector has an elongation tube terminating in a hood from 10 to 15 cm. above the perforated copper cylinders containing the bobbins (spools of 5 kilos.), which fit into the sleeves. The dye-liquor is sucked upwards and through the bobbins by the injector, which also acts as heater, is sent up to the hood, and is thus kept in circulation. A number of these vessels are employed side by side for wetting out, mordanting, and dyeing; the copper cylinders being transferred from one into the other by an overhead travelling crane.

The other modification is adapted for dyeing by the hyposulphite (thiosulphate) vat, and differs from the former in having the injector outside the vessel, returning into the latter by a bent tube which dips into the liquor to about 10 cm. to prevent air being sucked through the indigo solution. The injector is also surrounded by a counter-current cooler to maintain a temperature below 62° C.—I. S.

Alizarin-dyed Cotton Fabrics, Results of Analysis of. C. Liebermann and P. Michaelis. *Ber.* 1895, 28, 2264—2265.

A CONTINUATION of the author's examination of the alizarin lakes on cotton (this Journal, 1895, 514).

The following additional results have been obtained:—

Per 2,000 Sq. Cm. of Tissue.

Dark Red Lake.		Dark Purple Lake.		Chocolate Lake.	
	Grms.		Grms.		Grms.
Alizarin ("For Red")	0.2791	("For Purple")	1.0718	("For Purple")	0.6210
Al ₂ O ₃	0.0557	Fe ₂ O ₃	0.2377	Fe ₂ O ₃ +Al ₂ O ₃ ..	0.0638
SnO ₂	0.0108	" ..	" ..	Cr ₂ O ₃	0.3449
CaO	0.0626	" ..	0.1298	" ..	0.0639
Fatty acid, combined	0.0795	" ..	0.0571	" ..	0.0614
" free	0.0819	" ..	0.0514	" ..	0.1156

For the purpose of this investigation, in order to obtain a colour lake of a simpler character than the Turkey-red lake, the alizarin red was dyed upon a mordant free from fatty matters and tin. The presence of these substances in it, is accounted for by the fact of the colour lake having been cleared in a soap-bath to which an addition of a tin salt had been made.

The mordants were in each case fully dyed and the dyed tissues slightly souped.—E. B.

Dyestuffs, Artificial, for Dyeing Silk Fast, Systematic Review of. H. Werner. *Leipziger Färber Zeit.* 1895, 44, 453—454 and 469—474.

The dyestuffs available for dyeing fast colours on silk—*i.e.*, fairly fast on washing or fulling, or at any rate fast to water—may be classed in three groups, *viz.*:—

1. Mordant-dyeing dyestuffs, *i.e.*, such as give fast colours upon silk mordanted with metallic salts.
2. Dyestuffs developed upon the fibre.

3. Direct dyestuffs, which either by themselves alone give sufficiently fast dyes, or can be made faster by a suitable after-treatment.

For the classification of the different dyestuffs into their respective groups:

1. The mordants used are—

As chromium mordant, chromium chloride, sometimes the fluoride or acetate. As iron mordant, nitro-sulphate of iron. Chromium and alumina mordants are applied at 2°–4° B., iron mordants at 8°–12° B. Fixing agents, e.g., soap or soda, are sometimes added to the mordanting bath. The dyeing is performed in the usual manner.

2. The diazotising is effected with 4 per cent. of sodium nitrate and 8 per cent. hydrochloric acid. The developing is effected according to the colour required, with the different developers. In all cases the dyed material is soaped hot before dyeing and brightened with acetic acid.

3. Treatment with tannin, after dyeing, consists in entering the silk into a cold up to a hot aqueous solution of 40° C., containing 20 grms. of tannin in 1 litre, with an addition of 0.5 gm. of sulphuric acid, wringing or drying, and, without rinsing, entering a bath at 40° C., containing 10 grms. of tartar emetic per litre, turning for one hour in it, rinsing, soaping, and brightening if required.

Tabulated results are given, in which the dyestuffs are arranged in three groups, and at a glance the mordants or developers used, colours produced, and fastness respectively to water, washing and fulling, and boiling soap, are stated. (See also *Textile Colorist*, 18, [206], 33–35.)—T. W.

Chlorine Water, Photo-Chemical Decomposition of, Influence of Hydrochloric Acid and Chlorides on the. E. Klimenko. Ber. 28, 2558–2564.

Equal volumes of chlorine water and normal solutions of various metallic chlorides or hydrochloric acid were mixed and exposed to sunlight in sealed glass tubes; at the same time comparative exposures were made with tubes containing chlorine water only. When the chlorine in the latter tubes had disappeared, the whole of the tubes were opened and the free chlorine which remained was determined.

Very little chlorine had disappeared from the tube containing hydrochloric acid, and the presence of the chlorides also had a retarding effect on the decomposition. In any group of metals, arranged according to the periodic law, the retarding effect of any one metallic chloride was proportional to its position in the group—sodium chloride having a greater retarding effect than potassium chloride, and calcium chloride than strontium chloride.—A. L. S.

PATENTS.

Printing Woven Fabrics or Yarns in Skeins, Improvements in or relating to Processes and Apparatus for. G. Markus, M. Baender, and F. Sicker, Warschau, Poland. Eng. Pat. 1691, Jan. 24, 1895.

A METHOD of block printing with bars mechanically carried on endless bands.—E. B.

Printing Calico and other Woven Fabrics of Cotton and Cotton Warps (Prepared with Beta-Naphthol), Improvements in. L. Rivett, Stockport, and R. H. Scott, Littleborough. Eng. Pat. 3905, Feb. 23, 1895.

BLUE, yellow, green, and black colours are printed, along with, for example, the red colour produced from diazotised *p*-nitraniline, on calico prepared with sodium β -naphtholate.

The blue is obtained with Prussian blue in admixture with oxalic or tartaric acid; yellow, with lead acetate or nitrate, and citric and tartaric acids; green, with a mixture of the blue and yellow colours; and black, with logwood liquor, gall-nut liquor, potassium ferrocyanide, and "nitrate of iron."

After being printed, the cloth is passed through a solution of potassium or sodium bichromate, and then washed "and otherwise treated as may be desirable."

Instead of β -naphthol and *p*-nitraniline, analogous compounds may be employed.—E. B.

Dyeing Apparatus, Improvements in. J. G. Haslam, Philadelphia, U.S.A. Eng. Pat. 4671, March 5, 1895.

AN invention which principally relates to apparatus forming the subject of Eng. Pat. 18,517 of 1893 (this Journal, 1894, 391).

The efficiency of the apparatus is increased by the addition to it of a third set of yarn-sticks intermediate between the upper and lower sets.

The construction and arrangement of the devices for raising and lowering the yarn-frame are modified, and an automatic valve is provided for the regulation of the supply of steam to the vat.—E. B.

“Potting or ‘Spungeing,’ Process for rendering Wool-Dyeings Fast to.” S. Pitt, Sutton. From L. Cassella and Co., Frankfurt-on-Main, Germany. Eng. Pat. 23,592, Dec. 9, 1895.

CERTAIN azo colouring matters (Naphthylamine black D, Naphthyl blue-black N, Anthracite black, Jet black, Sulphone black, and others) on dyed wool, change colour when subjected to heat, molecular scission of their azo groups taking place. With the polyazo colouring matters, this occurs step by step, amido-azo compounds being first formed and the wool showing the colours characteristic of these; thus, the black azo colouring matters derived from the amido-azonaphthalenesulphonic acids first change colour to red.

The change is prevented from occurring by applying to the wool, either during the process of dyeing or afterwards, 3–1 per cent. of its weight of copper sulphate, or, after dyeing, 5–8 per cent. of sodium chlorate.—E. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Manufacture of Hydrochloric Acid [from NH_4Cl of Solvay Process], Note on a Process for. O. N. Witt. Bull. de la Soc. Ind. de Mulhouse, Dec. 1895, 321.

It is pointed out that, while the ammonia process for manufacturing soda has advantages over the Leblanc process, it is yet necessary, in part, to use the latter in order to obtain the hydrochloric acid required in industry. The author proposes to obviate this objection to the Solvay process by a special treatment of the residual ammoniacal liquor, which contains also undecomposed sodium chloride. This liquid, from which sodium bicarbonate has been separated, instead of being decomposed by lime to recover ammonia, with loss of the chlorine present as useless calcium chloride, as well as of the remaining sodium chloride, is evaporated nearly to dryness, the escaping carbonic acid being collected for application in the main process. The partially dried salts are then heated in a suitable apparatus until the ammonium chloride has sublimed, leaving a residue of available sodium chloride. The ammonium salt recovered is gently heated in an apparatus, such as a Leblanc sodium sulphate furnace, with sufficient syrupy phosphoric acid to form a bi-basic ammonium phosphate, and the hydrochloric acid evolved is collected in the usual way. The heat is then sufficiently raised to set free ammonia, which is condensed, and the residue of phosphoric acid is dissolved in water for re-use. Thus, it is claimed that phosphoric acid plays the same part in the author's process as ammonia in the Solvay process; and that, as it is constantly regenerated, its cost need not be considered in view of the hydrochloric acid recovered by its means, at a cost enabling it to compete with that obtained in the Leblanc soda process.—E. S.

PATENTS.

Sulphuric Acid, Manufacture of, Improvements in the [Economy of Nitre]. U. F. Benker, Clichy, France. Eng. Pat. 1168, Jan. 17, 1895.

THE liability to the escape of yellow vapours from Gay Lussac towers in the manufacture of sulphuric acid is attributed to the presence in the gases of too much "hyponitrous acid," for which the absorbing capacity of sulphuric acid at 60° B. is feeble. The loss thus occurring is prevented, under this invention, by injecting moist sulphurous

acid into the last chamber of the series of chambers used in such manufacture, or into the portion of a large chamber serving as the last chamber of the series. The injecting apparatus is preferably made of an alloy of lead with 10 per cent. of antimony, and contains two injector cones, the outlet to which faces the aperture for discharge of the sulphurous acid (moistened by admission of steam through a fine platinum jet) into the chamber to the side of which the apparatus is attached. The flow of both sulphurous acid and of steam are duly regulated, according to the coloration of the gases issuing from the Gay-Lussac tower. It is stated that, in a large apparatus, 150 to 250 kilos. of nitrate may be saved daily by use of the described process.—E. S.

Cyanogen Compounds, Improvements in the Production of.
A. E. Morgans, London. Eng. Pat. 2660, Feb. 6, 1895.

CYANOGEN, or compounds of cyanogen with chlorine, bromine, iodine, or fluorine, are produced for the purpose of extracting precious metals from their ores. One method of obtaining cyanogen consists in electrolyzing potassium cyanide solution, using a carbon anode and an iron cathode. Or, a cyanide is treated with sulphuric acid in presence of manganese dioxide, and the hydrocyanic acid gas is led over manganese dioxide heated to about 250° F. Chlorocyanogen is produced by electrolyzing a mixture of sodium chloride and a cyanide; or by treating a mixture of sodium chloride, sodium cyanide, and manganese dioxide with sulphuric acid; or a mixture of bleaching powder and an alkali cyanide is acted upon by a suitable acid, such as hydrochloric acid. The compounds of cyanogen with bromine, iodine, or fluorine are similarly prepared by electrolyzing a solution of the respective salts, or by their decomposition by means of acid in presence of an oxidising agent. The cyanogen, or cyanogen compound, may be used direct, or be compressed into a liquid state for transport.—E. S.

Chlorine, Manufacture of, by means of Magnesium Chloride, Improvements in. T. H. Bell, Middlesbrough.
From T. Schloesing, Paris. Eng. Pat. 3489, Feb. 18, 1895.

THE inventor has already described in Eng. Pat. 11,821, 1887 (this Journal, 1888, 626), the conditions necessary for dehydrating magnesium chloride obtained in a granular state, and in the present invention he describes the apparatus required for carrying out this and related processes. The "grains" of hydrated magnesium chloride are heated in a series of superposed cast-iron cylinders through which a current of dry hydrochloric acid gas is passed. Each cylinder is traversed by a steel shaft carrying spiral blades, which in rotating, impel the grains in the uppermost cylinder towards an outlet, through which they pass into the cylinder next below, and so on until they are discharged into a receptacle. The partially dried grains are then heated to low redness in the fireclay grid of a muffle furnace of brickwork, through which dry HCl is passed. The same furnace may be used in effecting the decomposition of the anhydrous magnesium chloride by air, to obtain chlorine. Details of the construction are given and shown.

The hot and moist hydrochloric acid issuing from the torrefiers is passed through a series of carbons in which strong acid condenses. The remaining gaseous acid is led through coke-packed towers down which sulphuric acid is run, to render it anhydrous for re-use. A chamber is shown containing a series of heated pans in which the sulphuric acid from the towers is concentrated, the strong acid passing from the last of the pans into a leaden box set over a flue, to which is also admitted the strong liquid hydrochloric acid previously recovered by condensation. The gaseous HCl given off may be completely dried by passage through a sulphuric acid tower, ready for application in the process.—E. S.

Zinc Chlorides, Improvements in the Production of.
C. Hoepfner, Giessen, Germany. Eng. Pat. 5062, March 28, 1895.

Zinc oxide, such as that derived from the roasting of calamine and zinc blende, is digested with solution of

magnesium chloride or zinc chloride, and carbonic acid is passed in to throw down zinc carbonate, which may then be converted into zinc chloride by digestion with calcium chloride, as described in Eng. Pat. 11,724, 1891 (this Journal, 1895, 581). Zinc oxide may be treated with calcium chloride solution and at the same time with carbonic acid to obtain zinc chloride in solution and a precipitate of calcium carbonate. Residual liquors of the manufacture of sodium and potassium salts, and such as occur in the treatment of copper and nickel ores, containing calcium and magnesium salts, with or without iron salts, may be used in the process. Metals more electro-negative than zinc may be separated from solutions of zinc salts by electrolysis in the manner directed in Eng. Pat. 13,336, 1893 (this Journal, 1894, 741). Zinc oxide may also be dissolved by solution of a caustic alkali, and be precipitated as described, for conversion into chloride. The alkaline solutions may be used again and again. Sulphates of iron, magnesium, and other metals may be caused to react with sodium or potassium chloride at a low temperature, to obtain chlorides suitable for use in dissolving zinc oxide.—E. S.

Alkali-Chlorates, Improvements in the Electrolytic Manufacture of. J. Wetter, London. From The Elektrizitäts-Aktiengesellschaft vormals Schuckert and Co., Nürnberg, Bavaria. Eng. Pat. 7364, April 10, 1895.

IT is proposed to dispense with porous divisions between the electrodes, and to employ a solution of the alkali chloride saturated at ordinary temperatures. The electrolyte is worked at a temperature preferably from 40° to 100° C., with a current density of 500 to 1,000 amperes per square metre. 2 to 3 per cent. of potassium bicarbonate is added to the electrolyte to maintain alkalinity next the anode (free caustic is to be avoided), and periodically, carbon dioxide is admitted. Instead of carbonates, organic compounds (fatty acids, or oxy-fatty acids, especially acetic and oxalic acid or carbohydrates, such as saccharose, dextrose, or dextrin) may be added to the bath, yielding carbonic acid on their further oxidation at the anode. "The yield of chlorate is a maximum at the beginning of the process, and drops as the contents of chlorate increase. The process should therefore be interrupted as soon as the consumption of current for the further production of chlorate exceeds a limit determined by the cost of the motive power."—J. C. R.

Caustic Soda, Hydrogen, and Chlorine, Improved Process for Obtaining, by Electrolysis of Sea Water, and in Treating the By-Products obtained during such Process.
G. B. Baldo, Trieste, Austria. Eng. Pat. 18,406, Oct. 2, 1895.

SEA-WATER is evaporated to a specific gravity of 1.060, and then electrolysed. The anode is placed in a porous pot. The cathode is in the form of a pot surrounding it. These two are filled with the electrolyte. A third pot encloses these again, and forms a water or cooling jacket. The soda liquor produced in the cathode compartment is drawn off from time to time. The hydrogen is eliminated. The chlorine may be collected for use. "The residue in the porous pot contains chloride of sodium . . . and free sulphuric acid." This residue is subjected to distillation. The last quarter coming over contains dilute hydrochloric acid produced by the action of the sulphuric acid on the chloride of sodium. The dry residue is heated to redness and the acid vapours passed through barium chloride solution, and then through the weak solution previously obtained by distillation, to bring it up to the desired strength.—J. C. R.

VIII.—GLASS, POTTERY, ENAMELS.

PATENT.

Translucent Enamel, Improvements in. W. Lutwyche and W. B. Lutwyche, London. Eng. Pat. 5934, March 21, 1895.

THE inventors claim the use of the following materials in the proportions named for the production of translucent

enamel:—Boric acid, 80 to 100; zinc oxide, 50 to 80; stannic acid, 30 to 40; powdered flint, 50 to 60; fel-par, 5 to 10; pearl ash, 2 to 5; carbonate of soda (*Sel de St. Gobain*), 20 to 30; bone ash, 5 to 9; calcined borax, 8 to 12; nitre, 2 to 5; chloride of sodium, 5 to 9 parts.

For colouring the enamel blue, hydrate of alumina and hydrated protoxide of cobalt (*Bleu de Sèvres*) may be used; for black, the preparation of oxide of manganese known as *oxyde noir de Dubois*; for yellow, oxide of antimony or oxide of uranium; for pink, carmine.—V. C.

IX.—BUILDING MATERIALS. CLAYS, MORTARS, AND CEMENTS.

Cement Mortar, Influence of Character of Sand on. A. S. Cooper. *J. Franklin Inst.* 1895, 8, 321—339.

THE author has made numerous experiments on the influence of sands of varying fineness and character of grain on the tensile strength of cement-mortar briquettes prepared with them. He arrives at the following conclusions:—(1.) Other things being equal, a fairly coarse sand, *e.g.*, one passing through a 12 sieve (12 wires to the inch) and caught on a 16 sieve, gives mortars of higher tensile strength than do finer sands. (2.) This effect of size of grain disappears with sands fine enough to pass a 40-mesh sieve and caught on a 60-mesh sieve; sands finer than this give similar results. (3.) The character of the surface of the grains is of moment. Mere sharpness of grain is not the only point to be considered, for an extremely sharp sand may have a smooth surface on each facet, and a moderately rough surface is preferable.—B. B.

PATENTS.

Wood, Treatment of, with a View to Preserving and Colouring the same. R. Aitken, London. Eng. Pat. 2710, Feb. 7, 1895.

ALTHOUGH the lighter paraffin oils are said to protect timber, they disappear after a time through rain and climatic influences, leaving only the heavier oils in the wood, and these are sufficient to protect the timber from decay. The invention consists in taking the heavier oils or waxes of the distillation of mineral, animal, or vegetable oils and mixing them under pressure and at an elevated temperature with naphtha or other solvent. The solution is then forced into the wood in the same way as when creosoting is adopted, after which the naphtha is recovered from the wood by distillation, leaving the heavy oil in the timber to protect it from decay. By this means a small amount of heavy oil will thoroughly preserve wood, whilst the latter will be clean to work and handle, and remain light and elastic. It is claimed that only one-fifth the weight of heavy oil is required compared with creosote. For colouring the wood, such dyes are used as are soluble in the solvent employed to dissolve the oils, with which the wood is being treated.

—D. B.

Portland and other Similar Cement, New or Improved Process and Apparatus for the Manufacture of. E. H. Hurry, New Brighton, U.S., and H. J. Seaman, Catasauqua, Pennsylvania, U.S. Eng. Pat. 23,145, Dec. 3, 1895.

IN ordinary practice, the hot clinker is spread on floors to cool, a process which is wasteful of time and space, and also requires that a large amount of material shall always be undergoing treatment in the works, even for a moderate output. In the present invention, the hot clinker is broken into small pieces, then wetted by a stream of water, and passed through a rotating conduit, where it is subjected to a strong draught of air, which cools the material; so that by the time it reaches the end of the conduit, it is in a condition for immediate handling.—V. C.

Cement and Cement-Mortar, An Improved Process for the Manufacture of. M. Nahsen, Schönebeck, Prussia. Eng. Pat. 24,898, Dec. 28, 1895.

THE waste residues of the manufacture of sulphate of alumina are washed and partly dried by the aid of gentle heating,

about 25 per cent. of water remaining, and quicklime is added. In general, equal quantities of the dried residues and of quicklime, are used, but for hydraulic cement, the quantity of lime is less.—V. C.

X.—METALLURGY.

Certain Metals, Solution and Diffusion of, in Mercury. W. J. Humphreys. *Proc. Chem. Soc.* 1896, [159], 9.

THE author has examined quantitatively the solution and diffusion of tin, lead, bismuth, zinc, copper, and silver in mercury with a view to determining the extent to which these phenomena differ, if at all, from the solution and diffusion of non-metallic solids in liquids. Pieces of metal were placed on the upper surface of a column of pure mercury, and samples of the liquid were taken at definite depths below the surface, and the amount of foreign metal estimated. As far as the experiments go, the author concludes that the solution and diffusion of metals in mercury do not essentially differ from those of non-metallic solids in liquids. Copper and silver dissolve in mercury to a very small extent at ordinary temperatures, but diffuse very rapidly.

Nickel Carbonyl, A Method for Preparing. H. Fiey. *Ber.* 1895, 28, 2512—2514.

THE author has made the interesting observation that nickel carbonyl (together with carbon monoxide) is formed when metallic sodium acts on ethyl oxalate in presence of a haloid salt of nickel. The following process is adopted:—A mixture of finely powdered anhydrous nickel chloride, and sodium cut in small pieces, contained in a gas-evolution flask, is covered with petroleum ether, and heated on a water-bath at 90° C. Dry ethyl oxalate is then added drop by drop through a tap-funnel, and the gas evolved passed through a flask placed in cold water in order to separate volatilised ether, &c. The proportion of nickel carbonyl formed is small (less than 5 per cent.), but it is readily detected in the gas by its odour, and by the greenish tinge it imparts to the flame when burnt. Passed through a red-hot tube, the gas deposits a brilliant filix of metallic nickel. Attempts to prepare carbonyl compounds of other metals in this way failed signally, even in the case of iron.

—H. T. P.

Chromium Amalgam and some Properties of Metallic Chromium. J. Féré. *Comptes rend.* 121, 822—824.

THE author has obtained the amalgam of chromium by an electrolytic method which has not been previously employed. When a solution of chromium chloride is electrolysed, without special precautions, with a negative electrode of mercury, the mercury takes up but little chromium, and a brownish-black chromium oxide is formed in the liquor. The author used 160 grms. of crystallised chromium chloride with 100 grms. of concentrated hydrochloric acid and 740 grms. of water, with a current of 22 amperes. In this way it was possible to obtain 1½ kilo. of solid chromium amalgam in a very short time. The amalgam was washed with water, and the mercury pressed out by squeezing in chamois leather. For analysis the amalgam was heated in a current of oxygen, and the chromium estimated in the resulting oxide. This showed that the amalgam has the formula Hg₂Cr. On pressing it for some minutes between filter-paper, at a pressure of 200 kilos. per sq. centimetre, the amalgam lost mercury, and a fresh amalgam of the formula HgCr was obtained. This amalgam is harder than the first, but it changes in the air more readily, and its surface soon becomes covered with little drops of mercury. By distillation *in vacuo* at 300°, one of these amalgams yields a chromium of different properties to that obtained by Deville and Fremy. It fires spontaneously in the air, and absorbs at the same time both oxygen and nitrogen, the heat disengaged raising the whole mass to a red heat. In this respect it resembles manganese obtained in the same way. Heated in a current of nitrogen it becomes incandescent and forms chromium nitride. It absorbs sulphur dioxide in the cold, becoming incandescent,

and if heated very lightly in a current of either carbon monoxide or dioxide, it becomes red-hot by the reaction. The author proposes to further study the products of these reactions.—A. W.

Aluminium Solders. J. Richards. J. Franklin Inst. 1895, 5, 351—355.

AFTER many trials the author has found that an alloy composed of aluminium 1, phosphor tin (10 per cent.) 1, zinc 11, tin 23 parts by weight, is effective as a solder for aluminium. The zinc and tin in this solder approximate to the proportions required by the formula Sn_2Zn_3 . The solder is said to be capable of use with a soldering iron, and not to disintegrate after exposure to air, as is often the case with tin-aluminium alloys.—B. B.

Zinc, Sulphur and Carbon in. R. Funk. Ber. 1895, 28, 3129—3132.

THE proportion of sulphur in purified zinc is found to range from 0 to $2\frac{1}{2}$ parts per 10 million; and the last traces may be extracted by continually remelting the metal and passing it through an asbestos filter. From this it would appear that sulphur is not appreciably soluble in molten zinc, but that when present in the metal it exists as sulphide. The test for traces of sulphur may conveniently be made by treating about 20 grms. of zinc with hydrochloric acid in a 200-c.c. flask, and collecting the hydrogen sulphide in the escaping gases by means of a sloping Pettenkofer's tube containing 12.5 c.c. of a 2 per cent. zinc sulphate solution mixed with an equal volume of 0.5 per cent. ammonia solution, and protected from the hydrogen sulphide of the air by a caustic soda guard-tube. When the zinc is quite dissolved (which may require a long time if the metal be pure, unless platinum wire is wound around it), the contents of the tube are transferred to a glass cylinder of 40 c.c. capacity, and the tube is rinsed with 2 c.c. of dilute hydrochloric acid; this is added to the now acid liquid in the cylinder, which is then diluted to 30 c.c. Finally there is added 1 c.c. of a solution of *p*-amido dimethylaniline in hydrochloric acid (1:500) and a drop of a 10 per cent. ferric chloride solution. In the presence of hydrogen sulphide a blue colour appears within a few minutes, which is quite permanent, and may be colorimetrically compared with other solutions of known strength. This colorimetric process, due to Fischer (Zeits. f. anorg. Chem. 9, 144), is accurate, and will detect 0.001 mgrm. of H_2S in 30 c.c. of solution. Commercial hydrochloric acid is never quite free from sulphur dioxide or hydrogen sulphide, and should therefore be boiled before use with a trace of potassium chlorate, the excess of chlorine being afterwards removed by the addition of pure zinc or of alcohol.

Traces of carbon were also found in zinc, but like sulphur, the carbon can be removed from the zinc by filtration of the fluid metal.—W. G. M.

Zinc-Fume Condenser, Explosion in. C. F. McKenna. Sch. of Mines Quart. 1895, 17, 171—174.

THE explosion referred to occurred in the condensers attached to a blast-furnace making spiegeleisen at the Passaic Zinc Company's works in Newark (N.J.). The blast-furnace in question was re-erected in 1893, and is 37 ft. to the stock line, with 6 ft. 9 in. hearth and 10 ft. bosh; it is water-cooled to the mantle, and has six tuyères with 3.5-in. nozzles placed 5 ft. 6 in. above the hearth. The capacity of the furnace is 2,323 cb. ft., and its daily output 20 to 21 tons of spiegel. It is charged through a bell and hopper, and is provided with a blast of 2,200 cb. ft. per minute at a pressure of 5 lb. and a temperature of 882° F. The zinc-iron-manganese ores of Franklin (N.J.) are used after the removal of a portion of the zinc. The zinc is reduced mainly in the lower part of the furnace, and is partly reoxidized, and escapes, together with much reduced zinc, in the form of the impalpable "blue powder," which sometimes contains 90 per cent. of finely-divided metallic zinc; a small portion is deposited in the form of concretions at the throat of the furnace, where a sudden lowering of temperature takes place.

The condensers are in duplicate, and are used alternately. Each set consists of eight clusters of nine vertical sheet-steel

pipes, connected at top and bottom with separate rectangular cast-iron chambers. The bottom boxes are 4 ft. 10 in. square, and 7 ft. 3 in. in height, but had been filled up to the extent of one-third by brickwork, as the capacity was too great, the brickwork sloping towards discharging-doors, 2 ft. by 3 ft., hung from the top in such a way that when the furnace is stopped they are free to blow open. At the top there are nine circular openings 11 in. in diameter closed by lids weighing about 50 lb. each, and also free to open outwards. From the last box in the set a gas flue 36 in. in diameter leads to the stove and boilers. On the morning of the accident, the furnace was stopped, and the downcomer-valve changed so that the set of condensers, which had been in use for some days, was cut off. A door in the lower boxes was then propped open, and some of the lids on the upper boxes were opened, when a slight explosion occurred, which blew away the block from the lower door, so that this became closed. At once a tremendous explosion occurred, wrecking one end of the set, scattering broken castings, and covering the workmen with pyrophoric zinc fume in active combustion. No explosion of similar magnitude has been recorded before, but slight puffs of explosion have occurred in the horizontal pipes when air has leaked in through valves or cleaning-holes. The combustion of zinc-powder, however, is not continuous. The air on the morning in question was humid, but the condensers had often been changed previously without accident under quite similar conditions. It would seem probable that the composition of the gases in the condensers was just suitable for forming an explosive mixture with the air introduced, and that the mixture was fired by the first particle of zinc which was pyrophoric, whilst the presence of moisture, leading to the formation of hydrogen by contact with the zinc dust, may have aggravated the disaster. Since the accident the condensers have been cooled before opening, but slight explosions have occurred even then. At present the doors and lids are operated mechanically from a safe distance, and the residual gases are swept from the condensers as quickly as possible after the set has been shut off. A pressure of 20 tons consolidates the blue powder (fume) to a metal-like material which oxidises with difficulty; otherwise the blue zinc powder may fire spontaneously, even in the cold.

—W. G. M.

Dust and Fume, Metallurgic, Methods for Collecting. M. W. Hes. Sch. of Mines Quart. 1895, 17, 97—118.

THE author classifies the methods employed in collecting fume in five classes:—

(1.) *Those in which it is deposited by its own weight in long flues, with or without enlarged settling chambers placed near to, or distant from, the furnace.*—Such chambers may collect dust, which consists merely of fine broken particles, but are never completely successful with fume, which is infinitely finer than dust, and is produced through the agency of heat. The collection is most perfect with long flues which have a large surface, and as many angles and turns as possible; the changes of direction are frequently made by the introduction of baffles, but the resulting interference with the draught of the furnace may seriously affect the output, and may even occasion a greater loss than the sacrifice of all the dust and fume produced; this is especially the case in roasting furnaces, in which dependence is placed upon chimney draught. The most elaborate system of dust chambers in the world is probably at Mecklenburg (Germany), and although much fume containing 70 per cent. of lead is recovered, yet even here the loss is very great. It may be said that almost all flues in metallurgical works should be higher and wider than they at present are; for the velocity of the gases containing metalliferous particles is nearly always too great; whilst almost universally in such works, economy would result from the substitution of fan draught for chimney draught. The Dee Bank Lead Works (N. Wales) had flues two miles in length; in Germany the flues are in one instance three miles long; all the lead smelters in Utah employ long dust chambers, whilst the Pueblo smelters, treating argentiferous lead ores, use simple cast chambers, and the lead smelters in Leadville (Colorado) and the copper smelters at Butte (Montana)

have short flues, few and simple. The system adopted by Enrich, of the Chicago and Aurora Smelting and Refining Company (Illinois), is specially commended: the smoke from his blast furnaces passes through a sheet-iron pipe, 7 ft. in diameter, with hopper-shaped receptacles to receive the deposit, and sliding doors beneath; after passing this pipe, it is joined by the smoke from the refining plant; and the mixed gases are conducted through a long underground dust chamber, with stone walls and a brick roof, and with 1-in. brick partitions built transversely nearly to the centre, from the left- and right-hand walls alternately, so that the fume is caused to take a devious path during its progress through the chamber; dwarf transverse walls are also built at intervals to a height of 2 ft. from the floor, to check the drifting of deposited fume along with the gaseous current. Iron pipes are cheaper than brick chambers, whilst they cool the gases more, and collect a larger proportion of fume; but they must be well painted. The author finds that the best paint for all iron surfaces is that known as silico-graphite paint, ground in oil, thinned with boiled linseed oil, and with a sufficient addition of No. 2 dryer. Comparing American with European practice, it may be said that the flues in the former case are measured by feet, in the latter case by miles.

(2.) *The filtering of the dust through flues, towers, or chambers, containing brushwood, coke, coarsely woven fabric, &c.; with water in jet, spray, or intermittent stream, to prevent clogging.*—Brushwood has now been generally abandoned as useless; coke is but little better, except for the short time which elapses before its pores become choked. Wire screens are always unsatisfactory. The use of water has never proved successful, owing in part to the difficulty of mixing fume and water. A system of coke filters has been employed at Balbach's works (New Jersey), but the author does not recommend any method in this division.

(3.) *The forcible projection of steam or drops of water into or across the current of smoke.*—The main difficulty in these processes is due to the solution of sulphur dioxide in the water, and the formation of liquids which attack the mortar and brickwork, or the iron of the flues. The best system consists in passing the smoke sinuously through a long underground flue, and then upwards through a compartment in a brick chamber 10 ft. wide by 20 ft. long by 12 ft. high; thence, passing over the top of the partition wall, it is led downwards through a series of 4-in. drain tiles supported on planking, and upwards again over similar tiles, being finally forced by 90-in. Sturtevant fans through a long wooden tuck with hanging curtains (which force it into close contact with the water), and a short chamber, to the brick stack. In the two tiled compartments and the curtained tank the smoke is subjected continuously to the action of water spray. Such a system was used by the St. Louis Smelting and Refining Company, and the smoke issuing from the stack was but slightly misty in appearance. The author would prefer a double set of condensing chambers, which could be used alternately, and would build them of glazed brick and heavy spar mortar.

(4.) *Passing the smoke through water; and (5.) passing it through water in which wire gauze diaphragms are immersed.*—The former method proved a failure, and is obsolete. Experiments, reported successful, were tried for the Sheffield Smelting Company by French and H. J. and J. W. Wilson, who forced the smoke through a 7-in. depth of water, containing a number of horizontal copper-gauze diaphragms, with 15 meshes to the linear inch: using a Root's blower absorbing 2.5 to 3 horse-power for the gases from a furnace smelting 15 tons of lead ore per diem. Oil and pyroligneous acid have been found more successful than water in retaining the dust, where no gauze baffles have been employed. The condensed matter obtained by these methods is not in a desirable form, and there would be difficulty in handling 250,000 cb. ft. of gas per minute, as is frequently necessary.

(6.) *The use of metal plates, hung in dust chambers, parallel to their length.*—This system has been used at Ems (Amer. Inst. Min. Eng., February 1883). The method

is only successful in long chambers (*cf.* Eng. and Mining J., July 1, 1882).

(7.) *The use of static electricity.*—Lodge's suggestion of passing high-tension electrical discharges through the fume has been tried on a practical scale at Bagilt (N. Wales), in the works of Messrs. Walker, Parker, and Co., but has been abandoned, because, although the deposit was effectually and rapidly produced in a closed chamber, no deposition occurred when the method was applied to the gases in motion in the flues; the temperature of the gases had no influence on the result, and the effect of moisture was excluded. The author is of opinion that this method may be made successful, and urges the reduction of speed by introducing a system such as that described by Cowper (Just. C.E. 1892-93, 112, Part II.) in a discussion upon papers by Collins and Malcolmson. This consisted in causing the furnace gases to divide themselves between a large number of flues placed parallel to one another, and communicating by small apertures with the main furnace flue at the one end and with the stack flue at the other. A plant of this nature put up in Spain had collected 190,000 lb. of fume in six months.

(8.) *Filtration through cloth or other textile fabric.*—The filters are usually in the form of bags of coarsely woven muslin or canvas. For business reasons the author gives no account of these systems, but appends a short bibliography, and refers to the Bartlett zinc-lead process (*see* this Journal, 1894, 13, 41).—W. G. M.

Copper and Concentrated Sulphuric Acid, Reactions between. C. Baskerville. J. Amer. Chem. Soc. 1895, 17, 901-912.

THE reactions between copper and strong sulphuric acid may be classed as primary and secondary; and in regard to the latter, the author's work accords in the main with that of Pickering (J. Chem. Soc. 1878, 33, 112). The primary reactions are—

(which may be regarded as taking place in two stages,—

although no hydrogen could be detected in the evolved gases); and (2) $5\text{Cu} + 4\text{H}_2\text{SO}_4 = \text{Cu}_2\text{S} + 3\text{CuSO}_4 + 4\text{H}_2\text{O}$. Using sulphuric acid of 1.84 sp. gr. and copper ribbon, in an atmosphere of hydrogen or carbon dioxide, it was found that the former reaction predominated at temperatures between 0° and 270° C., the proportion of the mixture reacting according to equation (2), increasing from 0° to 100°, reaching a maximum at from 100° to 130°, and then decreasing up to 270°, when only reaction (1) was in operation, and no black residue was formed. At temperatures below 100°, only the primary reactions occurred; but at higher temperatures a prolonged action generally led to secondary effects, and always did so as soon as the whole of the free copper had been dissolved. The black deposit formed according to equation (2) has been observed and differently interpreted by Berzelius and others, but the authors find that in nearly all cases it is practically pure Cu_2S .

The secondary reactions result from equation (2); they are (numbered serially)—

As might be expected, these reactions take place simultaneously, but in varying proportions. By experimenting at 140°-150° C., using an excess of copper, all the primary and secondary actions were observable, and sulphur was deposited on the sides of the flask, whilst an excess of sulphur was found in the cuprous sulphide formed. No hydrogen sulphide could be detected, and the occurrence of sulphur on the flask walls is apparently due to the sublimation of sulphur produced by the direct decomposition of sulphuric acid.

In one instance, where copper strips were one-third immersed in the acid at 250° C. in an Erlenmeyer flask from which the air had not been removed, the black residue

consisted of an almost pure oxysulphide having the formula $\text{CuO} \cdot 2\text{Cu}_2\text{S}$.—W. G. M.

Tellurium, Its Separation from Copper Residues. C. Whitehead. J. Amer. Chem. Soc. 1895, **17**, 849—855.

THE extremely refractory character of telluride gold ores has rendered it customary to smelt them with those of lead or copper. In the Western States of America the copper ores, to be treated economically, are smelted with gold- and silver-bearing ores, which act as flux, and, by yielding their precious metals, more than cover the cost of refining the copper. The mattes, containing much tellurium, are Bessemerised in the wet, and the copper is brought east for electrolytic refining. This copper contains from 98.5 to 99.5 per cent. of copper, about 100 oz. of silver, and 0.3 oz. of gold per ton, together with some arsenic, antimony, lead, bismuth, selenium, and an average of 0.04 per cent. of tellurium. It is doubtful if any copper, as produced, is free from tellurium, unless it be the native copper of Lake Superior. In electrolytic refining, the Hayden process (this Journal, 1895, **14**, 756) is largely employed. The black slimes deposited in the vats are separated from the coarser copper by screening, and are boiled with a 20 per cent. solution of sulphuric acid in a lead-lined tank by means of live steam so injected as to carry in air with it. In this manner practically all the antimony, arsenic, and bismuth pass into solution, together with copper, oxidised either initially or through the action of the injected air. After an hour's boiling, a solution of silver sulphate is run in, and steam is applied for some minutes, until the whole of the remaining copper has passed into solution by displacement of silver; excess of silver sulphate is then removed by the addition of fresh slimes. The residue, consisting of gold, silver, tellurium, and lead sulphate, and no longer slimy, is separated by drawing off the liquid, and, after washing well, is filter-pressed. The press-cakes are then dried in an oven, and melted on the Portland cement bed of a furnace, in which the metal is subjected to the action of an air-blast, whereby portions of the tellurium and selenium, and all but a trace of the lead present, are removed. The resulting bullion is poured into shoe-bars of about 300 oz. each, and is approximately 950 fine in silver, with 10 parts of gold. After cooling, the bars are dissolved in hot sulphuric acid in a cast-iron kettle; and, when solution is complete, the liquid is cooled and allowed to stand for several hours, during which the gold precipitates, and the tellurium crystallises in white, lustrous crystals of tellurous oxide. The first portion of the clear liquid drawn off is precipitated by copper, and the silver is melted into bars 990 fine, the remainder of the solution serving to treat a fresh batch of slimes. When several hundred ounces of gold and tellurous oxide have collected in the kettle by accumulation, they are removed, washed with dilute sulphuric acid to extract silver, copper sulphate, and tellurous oxide, and afterwards with strong sulphurous acid to dissolve the last traces of silver and tellurium. After cooling and settling, the acid is drawn off, and the residue is washed until free from tellurium and silver sulphates: the gold is melted with borax and nitre to eliminate remaining traces of lead and tellurium, yielding a metal 990 fine, of which the impurity is silver. The tellurium is present in the washings from the gold as tellurous oxide or sulphate, and, after the removal of the silver as chloride, may be recovered either by precipitation with copper or by passing sulphur dioxide through the solution. The tellurium is precipitated as euprous telluride in the form of a black powder, by placing bars of copper in the solution and boiling with steam. The powder is dried, and any copper thus oxidised is removed by repeated treatment with 5 per cent. sulphuric acid. Any residual copper would subsequently combine with tellurium and cause loss. After drying, the residue is fused with three times its weight of sodium carbonate and one-fourth its weight of charcoal. The sodium telluride is dissolved out with boiled water, and the tellurium is precipitated as a galena-like grey powder by passing into it a current of air. The tellurium is filtered, boiled with dilute hydrochloric acid to remove iron, alumina, &c., washed, and boiled for several hours with strong

potassium cyanide solution to remove the selenium and most of the gold present.—W. G. M.

"Fontes" and Alloys of Nickel and Cobalt, An Improved Process for the Desulphuration of. H. H. Lake, London. From P. Manhes and La Société Anonyme de Metallurgie du Cuivre, both of Lyons, France. Eng. Pat. 3959, Feb. 23, 1895.

IN the manufacture of nickel from siliceous ores, a "fonte" of iron and nickel is obtained, containing a small percentage of sulphur. To remove this sulphur and obtain an alloy of iron and nickel, the "fonte" is melted in any convenient manner with a quantity of lime or soda, mixed with the chloride of calcium or sodium. These reagents are preferably used, but the oxides and chlorides of other allied metals may also be employed.—A. W.

Heating Metal Sheets [Tin-Plate Works], Furnaces for, Improvements in. T. R. Ludford, S. R. Davies, and R. Davies, all of Llanelly. Eng. Pat. 4015, Feb. 23, 1895.

THE firegrate is placed at the back of the furnace and the flames and hot gases therefrom are made to pass through a flue built immediately underneath the entire bed of the

chamber in which the plates are to be heated. The gases travel to the front end of the furnace, through three vertical flues into this chamber, back again through it over the top of the plates, and finally up a shaft built above the fire-grate. Uniformity of temperature is the chief object of this arrangement. The grate and the shaft are connected by a flue, with a damper to be opened if desired. The plates to be heated are made to rest on a kind of grating placed on bearers on the floor of the heating chamber, and the furnace is provided with the usual doors and dampers.

Smelting Metals, Improvements in Furnaces for. L. Rousseau, Paris. Eng. Pat. 5513, March 15, 1895.

AN upper ring is fitted on to the top of a crucible as a continuation; the ring is perforated so that all the products of combustion may pass through into the top of the crucible itself, which thus becomes a combustion chamber. An oscillating furnace is described, to which this device is especially well adapted. This furnace is half sunk, and is supported over a closed ash-pit in such a way that it may be oscillated on trunnions. The outer casing is of metal, and is lined first with masonry and then with a thin layer of plumbago. The crucible is supported on the fire-bars by a plumbago block, and is kept in position by wedges placed between the crucible and the furnace lining. The top of the annular space between the two is closed, but apertures, provided with covers, are left for the introduction of fuel. All the products of combustion thus pass through the apertures in the crucible and continuation-ring already described; and the crucible itself has no lid. The ash-pit being closed, air is discharged into the space beneath the furnace through a bent pipe. A support is provided for the ladle, and a movable cover is placed over an open portion of the ash-pit (separated from the blast chamber by an iron partition) to facilitate arrangements for pouring.

Galvanisers' Flux Skimmings, Improved Method of Treating to Recover Ammonia and Facilitate the Extraction of the Zinc, with Apparatus for Use therein. C. G. T. Bennett, and E. H. Shortman, Pelsall, Staffordshire, and B. Bracey, Bristol. Eng. Pat. 5958, March 21, 1895.

GALVANISERS' flux skimmings are finely powdered and charged into a closed heated horizontal cylinder, in which is fitted a revolving shaft carrying an agitator. A proper proportion of milk of lime is run in to liberate ammonia. A large iron pipe, charged with cinders, is set upright on the cylinder or separator, through which the ammoniacal vapours pass, issuing by a tube on the top into a small enclosed tank, whence they pass into a cooling coil, flowing out as ammonia solution. The small tank is provided with a down pipe for returning to the separator any liquid condensed in it. By means of a valved tube, water can be run from the cooler on to the top of the cinders in the vertical pipe, to wash them when necessary. The contents of the separator are kept boiling and agitated until all the ammonia is removed, and are then run into settling tanks. The sediment is dried, and the zinc is extracted by ordinary methods.—E. S.

Plates (Metal), Coating with Tin, Terne, or other Metals or Alloys, Improved Method of and Apparatus for. H. J. Ridley, Llanelli. Eng. Pat. 6673, April 1, 1895.

A VERTICAL and a horizontal bath are described. In each instance the plates are removed from the bath between

corrugated metal plates, which act as rubbers, and two sets of rolls working in grease. The grease-pot is so contracted at the lower part that there shall be the minimum of contact between the metal bath and the fat; and a special heating or cooling chamber is provided for regulating the temperature of the grease. In the horizontal plant, the bath is covered with a lid, the central portion of which is depressed so that it is beneath the level of the molten metal, whilst the two end portions are removable in order that access may be had to the bath, to effect the removal of dross as it is formed.—W. G. M.

Basic Slag, Improvements in the Preparation of, for Fertilising Purposes. W. Hutchinson and A. Hickman, both of Wolverhampton. Eng. Pat. 6112, March 25, 1895.

Gold and Silver, Improvements in Extracting, from Ores and the like. J. S. MacArthur, Pollok-shields, and J. Yates, Glasgow. Eng. Pat. 6802, April 2, 1895.

THE apparatus consists of a barrel or closed cylinder lined with wood, and set horizontally with a shaft running through its centre from end to end. On the shaft, inside the barrel, are fixed amalgamated corrugated plates. The whole is so arranged that, by the revolution of the shaft, the barrel or the plates, or both of them, may be made to revolve with it. The finely pulverised ore is introduced into the barrel through a door in its side, together with water or a weak solution of cyanide, and the whole is then agitated until the amalgamation is complete. In the case of cyanide solution being employed, the contents of the barrel are afterwards run into a tank, the liquor separated, and the gold recovered therefrom by any known method.—A. W.

Alloys (Improved) of Refractory Metals with more Fusible Metals, An Improved Process of Manufacturing. W. P. Thompson, Liverpool. From La Société Neo Métallurgie Marbeau, Chaplet, and Co., Paris. Eng. Pat. 7847, April 19, 1895.

ALLOYS of chromium, molybdenum, or tungsten with iron, copper, or other metal, are made by introducing the metals or their oxides, simultaneously or successively, into an electric furnace, which is heated by horizontal carbons in such a way that the electrodes do not come into contact with the materials under treatment. The process is intended mainly for the production of alloys containing high percentages of the refractory metal, which may then be used to make the more ordinary alloys in the usual way.

—W. G. M.

Brass and other Metal Turnings and similar Fine Metal Scrap, Improvements in Means for Facilitating the Smelting of. R. Baumann, Seebach, Switzerland. Eng. Pat. 23,817, Dec. 12, 1895.

THE turnings are melted in a crucible placed concentrically within a refractory casing, with radial distance-blocks at the lower part to prevent eccentricity. The whole arrangement is placed over a smelting furnace, so that the waste gases from the latter may pass through the annular space around the crucible. At the upper part of this space, solid segmental covers may be introduced, partially to cover the aperture and so control the flow of the heated gases, and hence to regulate the temperature of the furnace.

Electro-Chemical Decompositions, Metallic Mixtures and Alloys for Effecting. O. Imray, London. From L. Diehl, Hamburg, Germany. Eng. Pat. 2804, Feb. 8, 1895.

MIXTURES of different metals are employed which, when added to liquids, act as voltaic couples. These may be comminuted and mixed in various proportions, but it is preferred to fuse them together to form a more or less imperfect alloy, and then use this alloy in small fragments, shavings, filings, or other forms presenting an extended surface. These mixtures or alloys may be immersed and agitated in the liquid to be decomposed, or arranged so that the liquid percolates through them. For gold-carrying solutions, percolation in an upward direction is best. For the evolution of hydrogen in neutral solutions (hot or cold water), an alloy is prepared of lead, 10; aluminium, 30; tin, 20; zinc, 50 (*parts*). For the precipitation of gold and silver from their cyanide solutions, an alloy is preferred containing aluminium, 5; lead, 5; zinc, 90 (*per cent.*), if the cyanide solution contain about 0.1 per cent. or more of cyanide; and an alloy of aluminium, 10; lead, 5 to 7½; zinc, 82½ to 85 (*per cent.*), if the solution contains less than 0.1 per cent. of cyanide. For the weakest solutions it is useful to add to the alloy a small quantity of tin, say about 1 per cent.—J. C. R.

Batteries, Secondary Voltaic, Improvements in. L. Epstein, London. Eng. Pat. 21,516, Dec. 21, 1895.

CELLS are made of "light weight"; provision is made against short-circuiting by fragments of the active material and loss of mercury from amalgamated plates. Claims: (1) "In a secondary voltaic battery, casings enclosing the positive plates, and extending below them, their walls being porous except in their lower parts . . ." (2) "In a

secondary voltaic battery having negative plates coated with zinc and mercury amalgam, troughs holding the lower edges of the negative plates . . ."—J. C. R.

(B.)—ELECTRO-METALLURGY.

Iron and Steel, Permeability of [Magnetism]. M. Osterberg. *Sch. of Mines Quart.* 1896, **17**, 118—127.

THE causes of variation in the magnetic permeability of iron are:—Chemical composition, temper, temperature, rapid magnetising and demagnetising (frequency), and previous history of the specimen. Samples of steel made by the basic open-hearth process, and containing, C = 0.07, Si = 0.053, P = 0.008, S = 0.032, and Mn = 0.22 per cent., are compared with acid open-hearth samples containing C = 1.406, Si = 0.077, P = 0.032, S = 0.032, and Mn = 0.470. Permeability curves were obtained for each of these metals after ordinary cooling, annealing, hardening followed by annealing, and hardening alone. From these curves and the accompanying numbers, it is seen that the harder the steel, the poorer is the permeability; all the low carbon specimens were superior to any of those with higher carbon, but it is noteworthy that the curves in the former case agreed more closely among themselves than did those of the latter, among which the hardened specimen was far inferior to the others. The harder the steel the more definite will be the curve. Only at temperatures approaching 400° to 600° F. does the iron begin to lose its magnetic properties, the loss being complete at 760°. Rapid magnetisation and demagnetisation heat the metal and cause loss by "hysteresis," and iron which has been repeatedly magnetised has a slightly increased permeability. (If a magnet be discharged, *i.e.*, if the current flowing through the solenoid be suddenly broken, a considerable time elapses before the magnet is completely demagnetised. To shorten this time, a current must be sent through the solenoid in the opposite direction, thus using up energy. The energy thus lost is called "the hysteresis loss.")—W. G. M.

Aluminium prepared by Electrolysis, Presence of Sodium in H. Moissan. *Comptes rend.* **121**, 794—798.

THE conflicting results obtained by those who have essayed the industrial employment of aluminium, are due to the differences in the purity of the commercial article. The author has shown that the metal often contains nitrogen and carbon, which materially affect its properties. He now finds that it sometimes contains sodium, which has an important effect on the preservation of the metal. The amount of sodium was obtained by placing aluminium filings in a bottle of the same metal, and adding water distilled in a metal still. This mixture was heated to boiling daily for two weeks, after which the solution was filtered, evaporated in a platinum dish, hydrochloric acid added, when there was quick effervescence of carbon dioxide, and the sodium converted into sodium chloride, which, after evaporating to dryness, was estimated with silver nitrate. In an old sample 0.4 per cent. of sodium was found; the amount in more recent samples varied from 0.1 to 0.4 per cent. When aluminium contains sodium it is attacked by cold water. If the same water remains for some time on a sheet of the metal it takes up the sodium, which reacts on the metal, forming sodium aluminate; this is decomposed by the water, when alumina is deposited on the metal, and the water becomes again alkaline, and again attacks the metal. In this way the decomposition becomes more rapid after a time, the water becoming more alkaline. The sodium also affects the alloys prepared from such aluminium. M. Riche has found that alloys of aluminium and tin decompose water at ordinary temperatures. The author prepared an alloy containing 6 per cent. of tin with aluminium very free from sodium, and found that after two months' immersion in *seine* water, aerated daily, it became coated with little specks of alumina, but did not produce any hydrogen. With alloys containing a higher percentage of tin, if sodium be present, the decomposition of the water is still more rapid. The non-homogeneity of aluminium seriously affects its preservation. If such aluminium be placed in water, especially salt water, little spots of hydrated alumina quickly appear, and

these are found to be formed round little centres of carbon, and are a frequent cause of the alteration of the metal. In conclusion, the author states that aluminium, which has a great tendency to form an electric couple with any other metal, should never be employed except by itself, and free from carbon, nitrogen, or sodium.—A. W.

Molybdenum Bronzes. A. Stavenhagen and E. Engels.
Ber. 1895, 28, 2280—2281.

A COMPOUND similar to tungsten bronze is formed by electrolysing fused acid sodium molybdate, prepared by melting together 10 parts of Na_2MoO_4 and $3\cdot2$ of MoO_3 , the substance resulting from this fusion having the formula $3\text{Na}_2\text{O}\cdot\text{MoO}_3$. This acid salt is fused in a platinum crucible with the aid of the blowpipe; and a current of $8\cdot5$ ampères and 1·9 volts is used, generated by three accumulators placed in series. The bronze separates quickly at the cathode in beautiful crystals, which must be washed with boiling water and dilute hydrochloric acid. Under water the crystals appear as indigo-blue needles with a metallic lustre, but on drying, the colour becomes darker and the lustre less. Under the microscope the needles are seen to be quadratic. They are soluble in alkalis, and in nitric acid and aqua regia, but not in hydrochloric or sulphuric acids. Their composition, as found by analysis, corresponds to the formula $\text{Na}_2\text{Mo}_2\text{O}_5$.—W. G. M.

PATENTS.

Zinc from its Ores, and Electro-Deposition of Zinc upon Iron or other Metal or Alloys, Improvements in and means to be Employed for the Obtainment of. The Cowper-Coles Galvanising Syndicate, Limited, and S. O. Cowper-Coles, London. Eng. Pat. 2999, Feb. 11, 1895.

BRIGHT deposits of zinc upon iron are obtained from the following electrolyte:—A gallon of water, zinc sulphate 35 ounces, iron (preferably ferric) sulphate 12 ounces. The electrolyte is fed with zinc dust, or the anode is made from a zinc ore, of zinc dust, a basic salt of zinc or zinc oxide. Commercial ferrous sulphate is converted into the ferric salt (by electrolysis at the anode and reduced by hydrogen at the cathode) by atmospheric air, oxygen, ozone, or bichromate of potash, or any other suitable oxidising agent. The articles to be coated with zinc may first receive an adherent coating of oxide by treatment with bichromate of potash solution, and be dried in an oven before placing them in the zincing bath. "The electrolytic oxygen, liberated when the zinc is deposited, prevents the formation of hydrogen compounds of zinc and consequently of zinc sponge."—J. C. R.

Electro-Deposition, Improvements in Apparatus for Use in. The Cowper-Coles Galvanising Syndicate, Limited, and S. O. Cowper-Coles, London. Eng. Pat. 4154, Feb. 26, 1895.

THE anodes and the articles to be coated make contact with conducting cross- or bridge-pieces, "girders," superposed but insulated from each other. These cross-pieces make contact at their ends with conductors running along the tank. The object is to bring the anodes and the articles to be coated into close proximity in a simple and convenient manner.—J. C. R.

XII.—FATS, OILS, AND SOAP MANUFACTURE.

Oils, Californian, Physical and Chemical Properties of. W. C. Blasdale. J. Amer. Chem. Soc. 1895, 17, 935—941.

THE author has carried out this investigation, first, with the view of the accurate determination of the limits of some of the standard constants of California olive oils; secondly, as a practical test of the application of the Babcock method

of determining adulterants in butter to a similar purpose for olive oil; and thirdly, a determination of certain constants of some new and undescribed oils of vegetable origin (compare Nos. 16 and 17). The following samples of oils have been examined:—

1. Pendulina 1st. 2. Pendulina 2nd. The difference between these samples marked 1st and 2nd is that the latter includes oil from the "pits" as well as from the pulp of the olives. A small amount of warm water was added to the "pomace" before pressing in the latter case. The oils, as received from the press, were repeatedly washed and filtered until clear. 3. U'varia 1st. 4. U'varia 2nd. 5. Rubra 1st. 6. Rubra 2nd. 7. Redding pieholine. 8. Nevadillo blanco 1st. 9. Nevadillo blanco 2nd. 10. Manzanillo 1st. 11. Manzanillo 2nd. 12. Yellow mustard seed. 13. Black mustard seed. 14. Walnut oil, prepared from the kernel of the English walnut (*Juglans regia*), grown in the southern part of California, by extracting with petroleum ether. 15. Acorn oil, obtained by extracting the fruit of *Quercus agrifolia* with petroleum ether. It is a deep brown fluorescent oil, solidifies at 10°C ., and on long standing deposits wax. 16. Pine-nut oil, probably from the fruit of *Pinus monophylla*; a brown drying oil with an unpleasant odour and taste. 17. California outmeg oil, from the fruit of *Tunioia Californicum*. 18—27. Nine samples of commercial salad oils.

These samples were subjected to the following determinations and tests:—

Specific Gravity.—This was determined in an accurately standardised pycnometer of about 50 c.c. capacity.

Index of Refraction.—Determined by an Abbe refractometer of the Zeiss pattern.

Thermal Degree.—The increment of temperature which results from mixing 15 c.c. of oil with 5 c.c. of concentrated sulphuric acid in a calorimeter with constant stirring, an initial temperature of at least 20°C . being employed.

Viscosity Test.—The author employs Babcock's method (Methods of Detecting Adulterations in Olive Oil; report of Olive Growers' Convention, San Francisco, July 1891). 15 grms. of oil are placed in a saponification flask with 30 c.c. of water containing exactly 7·5 grms. potassium hydroxide and 10 c.c. of alcohol, and heated on a water-bath until saponification is complete. The resulting soap is washed into a large evaporating dish, heated until the alcohol is expelled, and diluted to 500 c.c. at 15°C .; the viscosity of the solution is determined by means of a torsion viscosimeter. The results are calculated in terms of the number of grms. of sugar which must be added to a litre of water in order to produce a solution of equal viscosity. In the case of the two mustard-seed oils it was necessary to dilute the solution to one litre.

Saponification Number.—Determined by the standard method, using 2·5 grms. of oil.

Iodine Absorption.—The Hübl method was employed. The standard of the hyposulphite (thiosulphate) solution was based on pure potassium bichromate, according to the method of the Association of Official Agricultural Chemists.

Melting Point of Fatty Acid.—A drop of the fatty acid is dropped on a thin but wide glass tube, and allowed to solidify. This is attached to a bulb of a thermometer, placed in a water-bath, and heated to a temperature at which the fatty acid runs down the side of the tube.

Elaidin Test.—Pontet's method was followed, which involves the use of a freshly prepared solution of mercurous nitrate.

Millian's Test.—(Compare this Journal, 1888, 7, 593.)

From the values enumerated in the following table the author regards as successful the application of the viscosity test to the detection of adulterated olive oils; the variations in the figures obtained from the different samples of pure oil are considerable, but not so great as to admit of confusion with any of the adulterated oils. Mixtures of mustard and cotton-seed oil could not, however, be detected by this test. The method promises to be of value in detecting lard oil, for which there is at present no satisfactory specific test.

J. L. B.

Wool Grease, Composition of. L. Darmstaedter and J. Lifschütz. Ber. 28, 1895, 3133—3135.

The alkaline liquid obtained from the partial saponification of wool grease was evaporated to a thick paste and treated with dilute alcohol. A large portion of the brown mass was dissolved, leaving an insoluble crystalline residue, which the authors have examined. After washing with dilute and then with strong alcohol the residue was boiled with dilute sulphuric acid until all the fatty matter had collected on the surface as a soft grey mass. It was then suspended in water and thoroughly extracted with ether. The substance was thus separated into an insoluble and a soluble portion. The insoluble part crystallised from absolute alcohol is a white, tasteless, and inodorous substance, which is insoluble in water, ether, the mineral acids, and alkalis. It dissolves in warm concentrated sulphuric acid however, imparting a yellow colour to the solution, but it gives neither the cholesterol nor the iso-cholesterol reaction. It is easily soluble in acetic acid, acetic anhydride, and in hot alcohol, chloroform, benzene, &c. From dilute alcohol it separates with half a molecule of water of crystallisation, melting at 105° — 109° . It has the same composition as menthol, $C_{10}H_{20}O$, and appears to be a hitherto unknown alcohol belonging to the unsaturated series $C_nH_{2n}O$. The soluble portion crystallised from alcohol melts at 82° — 87° and has the composition $C_{11}H_{22}O$. It appears to be the next homologous alcohol of the above series, the one following being probably the lanoline alcohol described by Marchetti. The yield of the two alcohols amounts to 2.5—3.0 per cent. of the wool grease.

—J. S.

Spermaceti, Characters of. L. F. Kehler. Amer. J. of Pharm. 68, 7.

The United States Pharmacopœia requires that spermaceti shall possess a specific gravity of "about 0.943," and a melting point near 50° C. The author gives a table showing the result of the examination of 17 specimens, and he concludes that the melting point of spermaceti varies from 42° to 47° C., and that of cetin from 48.9° to 55.5° ; the specific gravity of spermaceti ranges from 0.905 to 0.945 at 15° , and its saponification number from 125.8 to 134.6, whilst the acid number varies with the age of the sample. Thus, it is pointed out, that the requirements of the United States Pharmacopœia would appear to correspond with the figures for cetin rather than with those for spermaceti.

Salts of Fatty Acids and Soaps, Behaviour of, in Presence of Water. III. F. Krafft and H. Wiglow. Ber. 28, 1895, 2566—2573. (Compare this Journal, 1894, 1207.)

In former papers it has been pointed out that on cooling hot soap solutions, acid sodium stearate is precipitated from a solution of the pure soap at a higher temperature than acid sodium palmitate, and this again at a higher temperature than acid sodium elaidate. It was also found that the separation of the solid acid soap or mixture took place at a temperature of about 15° — 20° C. below the melting point of the free acid. In the present communication the pure sodium soaps of various acids have been compared and the exact temperature of separation observed. The results are contained in the following table: in all cases one part of the sodium salt was dissolved in 100 parts of water:—

Sodium Salt of	Temperature of Separation.	Melting Point of Acid.	Difference.
Stearic acid.....	69.0	69.2	9.2
Palmitic acid.....	45.0	62.0	17.0
Myristic acid.....	31.5	51.5	23.0
Lauric acid.....	11.0	43.6	32.6
Elaidic acid.....	35.0	51.0	16.0
Oleic acid.....	0	14.0	14.0

The temperature of crystallisation of the soaps always lies below the melting point of the free acid, and the difference between both temperatures regularly increases on descending the homologous series.

In general, a soap can only exercise its full effect when it is dissolved in water, and the above table clearly shows why soaps rich in palmitic and stearic acids are best used in hot aqueous solution, whereas soaps containing oleic salts produce the required effect at the ordinary temperature. In performing experiments of this nature it is imperative that the carbonic acid in the air be carefully excluded, otherwise it will combine with the alkali formed on the hydrolysis of the soap, and hence vitiate the result.—J. S.

Salts of Fatty Acids and Soaps, Behaviour of, in Presence of Water. IV. F. Krafft and H. Wiglow. Ber. 28, 1895, 2573—2582. (Compare preceding Abstract.)

SIXTEEN soaps in general are nearly insoluble in water at 0° C., determinations of molecular weight by the cryoscopic

method are rendered impossible. The authors have attempted to determine the molecular weights of soaps by the ebullioscopic method, but without success. Sodium salts of the higher fatty acids, or the real soaps, on being dissolved in water, raise its boiling point, but if sufficient soap be added to form a concentrated solution, the boiling point falls to nearly the original boiling point of the water employed. On cooling such a solution it solidifies to a gelatinous mass. There is only one class of substances—namely, the *colloids*—which dissolves in water without affecting its vapour pressure, and hence the authors conclude that the sodium salts of the higher fatty acids, or the real soaps, are colloids.

—J. S.

Trimethylene Glycol; Occurrence as a By-Product in the Manufacture of Glycerin. A. A. Noyes and W. H. Watkins. J. Amer. Chem. Soc. 1895, **17**, 890—891.

By submitting an abnormally light glycerin from a soap manufactory to fractional distillation, first at diminished and then at ordinary pressure, a liquid boiling at 214° — 217° and with a specific gravity of 1.056 at 20° was obtained, the ultimate analysis of which agreed with that of trimethylene glycol. The compound probably resulted from the fermentation of glycerin after spontaneous saponification and prior to the addition of the alkali. Refuse house-fat formed a considerable part of the soap stock. The presence of the glycol might be a source of danger in the manufacture of nitroglycerin, since it reacts with nitric acid with explosive violence. It would be detected by the low specific gravity of the glycerin and by the high oxidation equivalent, as shown by the bichromate titration.—W. G. M.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A).—PIGMENTS, PAINTS.

Lead, White; Electrolytic Process of Manufacture.

R. P. Williams. J. Amer. Chem. Soc. 1895, **17**, 835—842.

This process, invented by A. B. Brown, of Boston, U.S.A., consists in electrolysing sodium or potassium nitrate solution in a wooden vessel divided by a porous partition into two cells, one of which contains a pig-lead anode, the other a copper cathode. The anode dissolves under the action of the current, forming lead nitrate, whilst alkaline hydroxide and free hydrogen are produced in the cathode cell, the copper being unacted upon. The two solutions thus obtained are drawn off and mixed; lead hydroxide comes down as a white precipitate, and an alkaline nitrate solution is left, which is available for use again as electrolyte. The lead hydroxide is finally mixed with sodium bicarbonate (or normal carbonate), whereby a pure lead carbonate is obtained; and the resulting sodium hydroxide has only to be recarbonated in order to render it available for use once more. The original alkaline nitrate solution may be of any convenient strength, but 1 lb. per gallon (10^3 B.) is recommended as being sufficiently concentrated. A plant capable of producing 500 lb. of white lead per diem has been in operation for several months in Cambridge (Mass.). The process is economical, as compared with the old system, inasmuch as it uses pig-lead without remelting, whilst there is not a residue of from one-half to one-third unattacked, as in the Dutch process; again, it is practically instantaneous, and effects a saving in material and labour. The white lead produced is globular, and so fine that no grinding is necessary. The electrolytic paint is found, after two years' experience, to be as durable and opaque as, and to have a covering power from 12 to 20 per cent. higher

than that of the Dutch paint. The practical failure of the French rapid precipitation process is said to be due to the low covering power of the product ("Clichy white"), resulting from its crystalline form, the superiority of the Dutch paint being due to its globular character. The new material being globular, and even finer in texture than the latter, has therefore an improved covering power.—W. G. M.

PATENTS.

New Powders to remove Paint and Organic Matters from Wood, Iron, Stone, and other Materials. G. J. C. M. Baron de Liebhafner, London. Eng. Pat. 4940, March 8, 1895.

Sodium carbonate, slaked lime, and permanganate are mixed dry, then made into a paste with water, and applied to the surface from which paint is to be stripped.—E. S.

Pigments or Lakes suitable for the Manufacture of Wall-Papers, Improvements in and connected with. C. Denecys, St. Petersburg. Eng. Pat. 16,398, Sept. 2, 1895.

The base of these pigments consists of strontium carbonate, instead of the usual barium carbonate or sulphate. It is claimed that the lakes so obtained are brighter in shade than when barium is employed, and also that a given weight of dye is able to stain a greater amount of base. When using diazo dyes, it is advisable to produce the colouring matter together with the strontium carbonate in one operation. The cold diazo solution is mixed with the necessary quantity of strontium chloride, and the alkaline solution of the phenol, &c., containing the requisite amount of sodium carbonate to precipitate the strontium, added with constant stirring.—F. H. L.

Improved Metallic Paint, and Method of Making same. R. A. Sloan, Liverpool. From "The Ineh Non-Corrosive Metal Co.," Baltimore, U.S.A. Eng. Pat. 17,786, Sept. 20, 1895.

This consists of a mixture of 2 parts of tin and 1 of zinc melted together and granulated, then suspended in oil, with a drier. The paint is said to resist "the action of water and the atmosphere, and is practically non-corrosive."

—F. H. L.

Compound or Material for Use in connection with Non-Oleaginous Protective Coverings or Paints. J. C. Sellars, Birkenhead. Eng. Pat. 24,063, Dec. 16, 1895.

This patent describes a composition to be used for filling up the cracks or pores existing in coverings produced as described in Eng. Pats. 1457 and 5291, 1895, which are made without oil. $\frac{1}{2}$ lb. of rosin are dissolved in 36 lb. of petroleum, and 9 lb. of creosote are added, ground wood or pigments being also employed if desired.—F. H. L.

Lead Oxide Making, An Improved Process of. H. H. Lake, London. From T. Benfield, N.J., U.S.A. Eng. Pat. 25,009, Dec. 31, 1895.

This is a process for oxidising metallic lead in the presence of water by the action of air or oxygen. The metal in a finely divided state is put into a cast-iron vessel provided with stirrers, which are made hollow, and through which a current of air is constantly passing. Water is added to cover the lead, and the agitators are set in motion. After a time, a cock placed in the side of the apparatus, some little way above the bottom, is opened, and the finer particles of the lead, already partly oxidised, are run off into a second vessel similarly constructed, where they are again treated with air or oxygen as before. The process is stated only to require a few hours to effect complete oxidation, and to yield a product free from crystalline structure. It is thus said to be a superior article for making lead chrome, carbonate of lead, &c.—F. H. L.

PATENTS.

Protecting Iron, Steel, and like Materials from Rust, A Process of and Means for. H. E. Newton, London. From "The Farbenfabriken vorm. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 4027, Feb. 25, 1895.

THE surface of the metal, either in the wrought or unwrought state, is washed with a 10 to 25 per cent. aqueous solution of hydroferro- or hydroferri-cyanic acid or a mixture of both, containing also, if desired, a small quantity of mineral acid; or the active ingredients may be mixed with alcohol, and 2 or 3 parts of oil, varnish, &c. added before application to the iron.—F. H. L.

French and the like Polishes, Improvements in and relating to. C. F. F. Bratsch, Berlin. Eng. Pat. 23,896, Dec. 13, 1895.

AFTER ordinary French polish has been applied to wood for some little time, it is apt to "bloom" or exude from the surface. This is stated to be due to the presence of "vegetable wax" in the shellac, which, together with the oil used in polishing, produces a soft, smeary substance, never becoming properly hard. To overcome this, the patentee removes this "vegetable wax" by repeated filtration of the polish, and also employs stick lac to replace part of of the shellac. His formula is:—Stick lac, 25 parts; shellac, 20; gum benzoin, 4; 95 per cent. alcohol, 100; and oil of rosemary, 1 part.—F. H. L.

(C).—INDIA-RUBBER, &c.

Caoutchouc and Gutta-Percha Substitutes. Chem. Rev. Fett u. Harz Ind. 1896, [34], 27—29.

VARIOUS substances and mixtures have been proposed for replacing gutta-percha as an insulating material for cables, but although many of them are effectual in other particulars, none have, so far, rivalled it in point of durability under prolonged exposure to the action of sea-water. Paraffin alone is too brittle, but the plastic products of the incorporation of ozokerite with small quantities of caoutchouc form a medium which in insulating power and durability, almost rival the latter substance in its pure state. The degree of insulation attained by Henly's cable, which is coated externally with ozokerite, is 5,000 megohms per knot. Nigrite, prepared by kneading together caoutchouc and the residue from the distillation of ozokerite, is far superior, both mechanically and as an insulator, to gutta-percha, and is less susceptible to heat than caoutchouc. The composition, consisting of a mixture of resin and heavy resin oils, used for the Brooks cable has a high insulating power, several samples having indicated regularly 19,000 megohms per mile. Wray's composition, made from caoutchouc, silica, powdered alum, and gutta-percha, is largely used in climates too hot for gutta-percha by itself, but is quickly attacked by sea-water.

Latterly, attention has been directed to balata (this Journal, 1894, 430) as a substitute for caoutchouc. This gum is obtained by tapping the balata tree, of which there are large forests in British Guiana and other parts of South America. There are two varieties—the red or "bullet tree," and the white, or true balata; they grow to a height of 90 to 100 ft. and can yield about $2\frac{1}{2}$ lb. of gum in a year without overtaxing their strength. The liquid gum soon hardens on the surface, which is then removed, and this continues till the whole has solidified.

For insulating purposes balata gum is inferior to caoutchouc, but it makes a good waterproofing material and is highly suitable for driving-belts. The trade is rapidly increasing, the exports from British Guiana having risen from 41,000 lb. in 1881 to 237,450 lb. in 1892. The industry is also being developed in Dutch Guiana under the auspices of some enterprising Americans.—C. S.

XIV.—TANNING, LEATHER, GLUE, SIZE.

PATENTS.

Animal Skins, New or Improved Process for the Treatment of. C. Marter and I. Levy, London. Eng. Pat. 1820, Jan. 25, 1895.

THIS invention applies especially to skins having particularly long fibres, such as those of the wild animals of the Dutch Indies and surrounding regions, and has for its object the rendering of the skins hard and transparent, so that they may be capable of being pressed or otherwise fashioned into buttons, &c. The raw skins are washed, dried, and stretched, and painted with an aqueous solution of "arsenic" containing about 1 gm. per litre. When this solution has dried, the skins are placed in cold water for from 1 to 15 days and then limed in three successive baths containing, say, $2\frac{1}{4}$, $4\frac{1}{2}$, and $6\frac{3}{4}$ kilos. of lime per 1,000 litres respectively. In the first bath, hair and flesh are loosened and may be subsequently removed, in the second the skins are degreased, and in the third they are hardened. The duration of the liming depends on the nature of the skin and on the desired degree of transparency. The skins may next be dyed and dried. They are finally immersed in two baths of linseed oil—which may be either cold, warm, or boiling, as found most convenient—for a period depending on the degree of hardness required; thus, from one to ten minutes immersion in boiling oil, or from a few hours to several weeks in cold oil, may suffice. Completion of the process consists in sponging with alcohol in order to fix the oil.—A. G. B.

Tanning Hides, Improved Process for. C. Kuees, Oshawa, Ontario, Canada, and D. W. Alexander, Toronto, Ontario, Canada. Eng. Pat. 22,714, Nov. 27, 1895.

THE unhaired and fleshed hide is treated in a pin wheel with a liquor consisting of bicarbonate of potash to the extent of "about 5 per cent. of the weight of the hide, $2\frac{1}{2}$ per cent. of sulphuric acid, 5 per cent. of the weight of the hide in neat's foot oil, and the balance of water," until it has become thoroughly permeated therewith. It is then transferred to another pin wheel, in which it is similarly treated with a liquor consisting of "10 per cent. of the weight of the hide of hyposulphite of soda, with sulphuric acid $7\frac{1}{2}$ per cent., 5 per cent. of neat's foot oil, and the balance of water." The hide is then left to dry. The order in which the compositions are applied may be the reverse of that here stated.

—A. G. B.

Sterilising Calgut and other Materials, Improved Process of and Apparatus for. J. Leman, Berlin. Eng. Pat. 23,504, Dec. 7, 1895.

CARGUT used in surgical operations is spoiled by steam sterilisation, and cannot be completely sterilised by alcohol and other substances hitherto tried. But exposure to the vapour of boiling alcohol containing 10 per cent. of water and 5 per cent. of phenol answers the purpose admirably, and does not damage the gut. The process is carried out in a suitable closed boiler having a condensing worm at the top to condense and return the vapours. Sponges and other materials may be sterilised in the same way.—L. A.

Hides and Skins in the Manufacture of Leather, A Process for Treating. A. K. Y. Anderson, St. Kilda, Melbourne, Victoria, and J. Mackintosh, Melbourne, Victoria. Eng. Pat. 24,950, Dec. 30, 1895.

THE raw hides and skins are soaked in cold water until softened. They are then rough-fleshed and soaked in water at a temperature of 27° C. for about half an hour. After having been drained, they are hung in an hermetically sealed vessel, into which carbonic acid gas is forced up to a pressure of about 30 lb. to the square inch. After an hour's sojourn in this chamber, the hair or wool will have become sufficiently loosened to be easily removed by unhairing knives. The pores of the skins are so opened by the treatment that tanning takes place rapidly.—A. G. B.

XV.—MANURES, Etc.

PATENT.

Basic Slag, Improvements in the Preparation of, for Fertilising Purposes. W. Hutchinson and A. Hickman, both of Wolverhampton. Eng. Pat. 6112, March 25, 1895.

To render the phosphoric acid more soluble when basic slag from the Bessemer or Siemens furnace is used as a fertiliser, it is mixed while molten in a ladle with about an equal quantity of molten slag from the blast furnace or from a cupola in which iron is being re-melted. The mixture when cold is ground to a fine powder ready for use. The proportions may vary from the above, the blast-furnace slag being reduced in quantity if the basic slag be very rich in phosphorus.—A. W.

XVI.—SUGAR, STARCH, GUM, Etc.

Sugar Industry, Advances in, for the Third Quarter of 1895. B. Cane-Sugar. Dingl. Polyt. J. 1895, 298, 138—139.

The yields obtained by Centrifugalsing Mascacutes.—H. C. Prijsen-Geerligs (Archief voor de Java Suiker industrie, 1895, III., 50) has carried out experiments, the object of which was to ascertain whether the differences of yield frequently observed when mascacutes—especially those from after products—are centrifugalsing can be ascribed to the different methods of boiling, cooling, and centrifugalsing. Very pronounced differences are observed when the yields, even of first product mascacutes from different factories, are compared. Every care should be taken during boiling to prevent the formation of false grain; it is, however, possible that fine grain may be formed in cooling down, and this would cause a loss during centrifugalsing. This latter occurs to a marked extent with after-product molasses which are not boiled with the object of forming grain. The size of the grain depends chiefly on the physical properties of the mother-liquor, small crystals being obtained from a viscous mascacuite. This partly applies also to first-product mascacutes, for the more impure these are, the smaller will be the grain that separates on cooling; and the greater, the loss on centrifugalsing. In mascacutes containing large quantities of invert sugar it has been found advantageous not to wait for the after crystallisation, but to centrifugalsing direct from the vacuum pan. With pure mascacutes this course is not advisable, since the after crystallising sugar adheres to the first grain, and so increases the yield. First product mascacutes should neither be too much nor too slightly boiled. The more rapid the cooling down the more viscous the syrup, the larger the amount of calcium salts, the finer the grain, and the smaller the yield. The author concludes from his observations with first as well as with second product mascacutes, that differences in yield are due to mechanical rather than to chemical causes.

In a paper on *A Method for the Rapid Detection of Magnesium Oxide in the Lime employed in Sugar Manufacturing* (D. Zuckerind. 1895, 20, 985), Prijsen-Geerligs states that there should not be more than 0.5 to 1 per cent. of magnesium oxide in lime, since the former has an injurious effect on the juice. He advises testing the lime for magnesia when the separation proceeds slowly, or when an abnormally large amount of the lime is needed, or finally when the thick juice has a bottle-green colour. The method employed is based on the fact that when ammonia is added to neutral solutions of calcium chloride no precipitate is produced; if however, magnesium salts are present a gelatinous precipitate of magnesium hydroxide separates, which is insoluble in water and ammonia, but soluble as a double compound in solutions of ammoniacal salts. 1 gm. of the lime is treated with 10 c.c. of water, warmed, and dilute hydrochloric acid added until nearly all the lime is dissolved, and the liquid is neutral or slightly alkaline. The solution is boiled to remove carbon dioxide,

filtered, and ammonia added. The presence of 1 per cent. of magnesia is sufficient to produce the gelatinous precipitate. When limestones are examined, 1 c.c. of lime water is added to the neutral chloride solution to precipitate iron and alumina, and ammonia added subsequent to filtration.

Heating Experiments with Fuels Employed in the Cane-Sugar Industry (D. Zuckerind. 1895, 20).—Carp has ascertained that the semi-gas furnace (Grundel's Patent) possesses the following advantages as compared with the ordinary fire-grate:—1. When dry bagasse is used more steam is obtained for a similar grate surface, and if the draught be properly controlled, economy of fuel is effected. Damp, or a mixture of damp and dry bagasse, can be burnt in emergency, although of necessity there is a diminished production of steam. 2. The fuel value of dry cane leaves (trash) is higher than that of dry Djatti wood (*teetonia grandis*) and only slightly inferior to bagasse. The semi-gas furnace is not so well suited as the ordinary grate for firing with dry cane leaves.

Crystallisation in Motion (Winter, D. Zuckerind. 1895, 20).—This author considers that with a general introduction of Bock's process of "crystallisation in motion," the Javanese cane-sugar industry may rival the beet-root sugar factories as to yield, and further that this process has more promise for the cane-sugar industry than the "diffusion" process. A number of points of advantage arising from the use of the process are dealt with; they chiefly have to do with increased purity, saving of time, and labour.

Lillie's Evaporating Apparatus (D. Zuckerind. 1895, 20).—This apparatus has recently been successfully introduced into Louisiana in place of the Yaryan evaporator, which likewise depends upon the film evaporation (this Journal, 1893, 745). The admission of thin, and running off of thick, juice is automatically regulated by floats and flap valves, which open more or less widely in proportion to the increase of the specific gravity of the juice. It is stated that in six minutes a 5 per cent. sugar solution can be raised to 30° B. The apparatus requires little attention, and causes no inversion of the juice.

Rational Treatment of Juice with Sulphurous Acid and Baryta (D. Zuckerind. 1895, 20).—Dupon has devised a new process based on the simultaneous application of lime and baryta. The experimental results show that sulphuration of the juice in presence of baryta improves its purity and salt coefficients, whereas sulphuration in presence of lime has the opposite effect. The following advantages accrue from sulphuration in presence of baryta. Sulphuric acid is completely removed from the juice, consequently the formation of incrustations is avoided. The greater portion of the lime salts are eliminated, so that an increase of purity—and salt—coefficient results. Most of the natural alkalis (potash and soda) are liberated, the alkalinity necessary for the preservation of the juice being thus secured.

Kruger remarks that baryta separates with difficulty and so hinders defecation, at the same time imparting some of its poisonous properties to the juice.—J. L. B.

Beetroot Juice, Gelatinous Separation in. F. Glaser. Centralb. Bakteriöl. 1895, 2 Abth. 1, 879.

THE so-called "frog-spawn" appearance in beetroot juice is generally ascribed to *Leuconostoc mesenteroides*. But the author shows that another bacterium which differs from *Leuconostoc* in not flourishing in a 10 per cent. neutral molasses, can also produce this phenomenon. The organism is known as *B. gelatinosum betæ*, and grows very readily in beetroot-juice gelatin. After 24 hours a plate culture exhibits white milky colonies which rapidly liquefy the gelatin. These colonies contain the bacteria; if the culture be fresh they are very motile, and when stained with methylene blue, appear as short rods frequently joined to one another. The bacteria develop with great rapidity from stored beetroot juice; after a few hours at the maximum temperature of 40° to 50° a slight evolution of gas occurs, and at the expiration of 12 hours the contents of the flask are covered with a gelatinous scum. Higher temperatures prevent the growth of the bacteria, yet they are not killed by prolonged heating of the infected juice at 100°. A similar growth appears more slowly in beer worts.

As stated above, this organism does not grow in a 10 per cent. molasses, but if the slimy precipitate obtained by the addition of alcohol to beetroot juice or its ash be added, development takes place. *Pari passu* with the gelatinous formation, inversion of the cane-sugar occurs and alcohol is produced in considerable quantity. The presence of lactic acid was not observed. The gelatinous mass possesses the properties of the so frequently described beetroot gums.

—J. L. B.

Carbohydrates, Action of Alkalis on. Conversion one into the other of Glucose, Fructose, and Mannose. T. A. Lobry de Bruyn and W. A. van Ekenstein. Ber, 28, [19], 3078—3082.

In their studies of the behaviour of glucose, fructose, and invert sugar towards alkaline salts of weak acids, the authors have discovered that very minute proportions of alkalis considerably affect the rotation of several carbohydrates. The influence thus exercised bears evidence to a certain degree of transformation, for glucose and fructose give as a result syrups which are almost inactive, whilst galactose yields a syrup of which the value of $[\alpha]_D$ is about $+30^\circ$, the respective normal values for $[\alpha]_D$ being about $+53^\circ$, -91° , and $+81^\circ$. It has been found, as the general result of a large number of experiments, that this change is due to reciprocal transformation of the different sugars one into the other. This has been established in the case of glucose, fructose, and mannose, each of these sugars being transformable under the influence of hydroxyl ions, alkalis, &c., into the other two.—W. S.

Megass and Refuse Furnaces. W. P. Abell. Proc. Inst. Civil Eng. 1895, 123, 3—10.

"The use of megass as fuel in the manufacture of cane-sugar has during the last few years become more general; and on many estates in the West Indies it has entirely replaced coal, of which 25 cwt. were formerly required for the production of 1 ton of sugar. During the years 1890—94, 520 furnaces were rebuilt in British Guiana at a cost of 50,000*l.*, the annual saving thus effected amounting to 100,000*l.*"

The moist megass (containing 50 per cent. of water), as it comes from the crushing rolls, forms about 28—31 per cent. of the whole sugar-cane, and when utilised as fuel fully satisfies, not only to evaporate the whole of the juice, but also to generate the power required for crushing the canes, curing the sugar, &c., without the assistance of any other fuel whatever.

Types of the furnaces employed—both of older and more modern design—are described in detail and illustrated by drawings.—H. T. P.

XVII.—BREWING, WINES, SPIRITS, Etc.

Wine, Technically Pure Glucose used in the Production of, Bearing thereof on the Detection of Adulteration. W. Fresenius. Zeits. Anal. Chem. 1896, 35, [1], 50—56.

It has been customary to infer the fraudulent addition of starch-sugar to wines during the process of manufacture, from the marked dextro-rotation of samples so adulterated, the dextro-rotation being due to the unfermentable and unfermented constituents (dextrin, isomaltose, dextrose) existing in ordinary glucose. Since 1892, however, the use of a certain proportion of "technically pure dextrose" (containing, as now obtainable, less than 1 per cent. of unfermentable matters) is permitted. It is pointed out that wines of this description, not being adulterated (*i.e.*, with common glucose), might yet be classed as such if they retain any appreciable amount of unfermented dextrose. To make sure that any excessive dextro-rotation observed is not due to dextrose, the wine should be completely fermented by means of beer-yeast (not pressed yeast, which has been shown to ferment dextrin, &c.) and again polarised. According to the author's experience, the dextro-rotation should now not exceed 0.3° , or 0.5° after evaporation to a syrup, precipitation with alcohol, and dilution to one-seventh of the original volume.—H. T. P.

See under XXIII., page 223.

PATENTS.

Yeast, Improvements in the Manufacture of. H. Elien, Rotterdam. Eng. Pat. 17,496, Sept. 19, 1895.

The patentee employs a dilute filtered solution of molasses or sugar syrup to which has been added the necessary quantity of phosphoric acid or phosphates for growing yeast. A moderately weak solution—about 16 or 17 kilos. diluted to 100 litres—is found to work best, and phosphoric acid—either free or as a salt—is added at the rate of about 0.4 to 0.8 kilo. P_2O_5 to 100 kilos. of molasses used. The solution should be filtered bright, and should preferably be sterilised before the addition of the seed-yeast, and the latter should be free from foreign organisms. The patentee claims to get a very pure and vigorous yeast.—L. T. T.

Brewing and Apparatus therefor, Improvements in. S. Kuhlmann, Hoxter, Germany. Eng. Pat. 23,997, Nov. 6, 1895.

The patentee believes he has discovered that the clouding of beer in casks arises from overheating of the wort in the brew-pan. The invention consists in employing jets of water or cold air to damp down the fire under the brew-pan when desired, and so prevent overheating of the wort.

—L. T. T.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY AND WATER PURIFICATION, DISINFECTANTS.

(A.)—CHEMISTRY OF FOODS.

Potatoes, Solanine in. G. Meyer. Arch. Exp. Path. Pharmacol. 1895, 36.

A SERIES of determinations of the solanine in potatoes before and during germination has been carried out by the author under the direction of Prof. Schmiedeberg, of Strassburg. Sound potatoes contained 44 parts of solanine per million; when peeled, the amount was only half as much. Young potatoes contained, between July and August, from 201 to 236 parts per million; Maltese potatoes only 50 parts per million. Whilst sprouting in a cellar between March and July, the solanine increased from 90 to 112 parts per million, and the sprouts contained from 2.72 to 5 per cent.

of the alkaloid, according to their length. Shrivelled potatoes contained 144 parts per million, whilst rotten ones covered with black fungus contained as much as 1,340 parts. Experiments with rabbits by Schmiedeberg showed that, with doses insufficient to cause vomiting, the mucous membrane of the stomach and intestine may be affected, without augmenting the tendency to pass into the stage of acute poisoning. Hence potatoes cannot have toxic effects unless the amount of solanine becomes unusually large under special and, indeed, unusual conditions. Nevertheless the results show that such influences may possibly be exercised.—W. S.

Tinned Iron Receptacles for Preserved Vegetables, Cause of the Black Coloration developed in. A. Rossing. Zeits. Anal. Chem. 1896, 35, [1], 38—50.

TINNED preserved vegetables, especially peas, are frequently spoiled, owing to the development of a blackish or brownish coloration, which first appearing on the metallic surface of the tin, then spreads to that portion of the contents in immediate contact therewith. The author states that this black stain generally consists of sulphide of tin—rarely containing iron—and concludes that its formation is due to the spontaneous decomposition of the organic sulphur compounds existing in all vegetables, whereby other bodies are produced (sulphides, mercaptans?) capable of acting on tin. Whether iron sulphide is ever formed is doubtful. The sludge of ferric hydrate occasionally observed appears to arise from the rusting of the iron wherever laid bare (the exposed edges at the joints in the side, top, and bottom of the tin). Air should therefore be excluded, as far as possible, by completely filling the tins with boiled water prior to sealing. The theory that the black stain is produced by free sulphur (and iron) derived from the rubber composition washers—now largely employed, instead of solder, to make air-tight contact between the tin and its lid—is shown to be erroneous. The rings are perfectly harmless.

The proneness to blackening exhibited by different vegetables depends, more or less, on their relative richness in sulphur compounds—with beans, for example, which contain very little sulphur, the trouble is rarely, if ever, experienced—and in any case is pronounced proportionately to their degree of ripeness or staleness. Hence it is of great importance that only young and perfectly fresh vegetables be submitted to the tinning process. Entire prevention of the trouble, however, can only be arrived at by the use of receptacles not acted upon by sulphur compounds, &c.; and in this connection it has been stated that tins, varnished inside, have proved perfectly satisfactory, even in the case of acid preserves.—H. T. P.

Butter, Testing of, by Viscosity Determinations. Pollenske. Apoth. Zeit. 11, 97.

See under XXIII., page 223.

PATENTS.

Casein, An Ammonium Compound of, The Manufacture or Production of. W. Majert, Falkenberg, Germany. Eng. Pat. 9, Jan. 1, 1896.

POWDERED dried casein is brought into contact with ammonia gas; or it is suspended in alcohol, ether, light petroleum, or benzene, and the gas passed through the liquid. The combination of the ammonia and the casein is accompanied with development of heat. The product is a white powder, permanent in the air, and readily soluble in water, forming a tasteless liquid, which is said to possess valuable nutritive qualities.—L. de K.

Peptonised Milk and Cocoa, An Improved Preparation of. W. H. Thew, Westminster. Eng. Pat. 4886, March 7, 1895.

THE inventor claims the manufacture of powder, or solid blocks or cakes of peptonised milk and cocoa, with or without sugar. The moist mixture (Eng. Pat. 14,965, 1894) is placed in shallow pans, heated by means of water

at 45°—55° C., so as to obtain a dry mass. Whilst drying, it is broken up by means of wooden spatules, and when dry enough it is reduced to powder by crushing or grinding.

If blocks or cakes are wanted, the powder is placed in suitable moulds and subjected to the required pressure.

—L. de K.

Soluble Albumen of Animal Food, A New or Improved Method of Obtaining and Preserving the. J. L. Johnston and Bovril, Limited, London. Eng. Pat. 6257, March 26, 1895.

THE object of the invention is to preserve the soluble albuminous matters of flesh without the use of antiseptics. The juice is separated from beef, mutton, &c., by means of hydraulic pressure, and collected in glass vessels. It is then spread over glass slabs or sheets and then allowed to dry at a gentle heat, which must, however, never get high enough to cause coagulation of albuminous matters. The dried mass is scraped from the glass slabs, and keeps for a lengthy period in air-tight packages.—L. de K.

Perishable Organic Substances, An Improved Method or Process for the Preservation and Storage of, by Cold. J. D. Postle, Sydney, New South Wales. Eng. Pat. 17,844, Sept. 24, 1895.

THE substance is first chilled by being brought to freezing point, and is afterwards thoroughly frozen to a depth of $\frac{1}{2}$ to $1\frac{1}{2}$ ins. Carcasses of sheep, &c. may now be packed as if frozen through. The arrangement for preventing thawing consists of an inner uninsulated chamber, all the walls of which are perforated for free circulation of air, and an outer insulated chamber having only one door. A fan works in the intermural space, and drives the air, which is directed by flanges and partitions, through every part of the inner chamber. A thermostat works a shutter in connection with a freezing coil so as to keep the air at a low and constant temperature.

The circulating air may be renewed by the automatic opening of a door, so that vitiated air may escape, whilst a door, where there is a partial vacuum caused by the currents of air, admits fresh and sterilised air. Thus fungoid growths on the surfaces of the carcasses are prevented.

—L. de K.

Green Vegetables and the Like, Improvements in the Preservation of. M. Braumann and A. Braumann, Wallhausen, Germany. From W. P. Thompson, London. Eng. Pat. 24,282, Dec. 18, 1895.

GREEN vegetables, such as cucumbers, beans, cabbage, spinach, &c., in the uncooked or unpickled state, can be preserved for a long time without the use of hermetically sealed vessels or a great cold, as follows:—

Cut salad, for instance, is placed in a perforated vessel lined with oak leaves, and a mixture of one part of sugar and four parts of salt is scattered over it. The bottom of the vessel is then covered with a lid and gently pressed. The mass is now placed in the forwarding vessel, the walls of which have been carefully rinsed with spirits of wine, and it is then again covered with a layer of sugar and salt.

—L. de K.

Bread Making, Improvements in or connected with.

R. L. Clarke, Reading. Eng. Pat. 20,978, Nov. 6, 1895.

3,516 PARTS of unmalted meal (Eng. Pat. 20,799, 1895) and 306 parts of malted meal (Eng. Pat. 20,798, 1895) are well mixed with a solution of 84 parts of bicarbonate of soda in 3,072 parts of water, to which 7 parts of hydrochloric acid of 1.142 sp. gr. have just been added. The mixture is then ready for baking.

If a fermented bread be required, the bran must be first removed and an aqueous infusion made of it at 150° F. for 30 minutes. This liquid is then filtered and used instead of the plain water. Instead of water, milk may be used; in this case the liquid need not be filtered, it being essential that the bran shall be retained.—L. de K.

Milk, An Improved Method of and Apparatus for Preserving. A. E. Jara, Santiago, Chili. Eng. Pat. 22,344, Nov. 22, 1895.

THE inventor claims a process for effectually preserving milk in tin cans without adding any preservatives, and without exposing it to the air during the process.

The fresh milk is at once filtered through charcoal into a tinned copper cylinder, and then forced through a tube furnished with a nozzle plugged with sponge, into a vacuum cylinder, which it enters through a spray in a state of fine division. The gases separate from the milk and collect in the upper part of the cylinder. A descending piston drives off the gases through a tube and subsequently forces the milk into a steriliser, where it may be heated by steam to 100° C. for seven or eight minutes. The milk is now driven by a second charge coming from the purifier into a refrigerator, where it is rapidly cooled to 0° C., and hence into an accumulator. The rapid heating and cooling are to keep the casein in an albuminous state. The cans are very shallow, so that the layer of cream may be thin; also the absence of air prevents churning. They are connected by tubes placed in a frame in the filling apparatus. Steam is first passed through until the cans are at the right temperature, afterwards milk until quite full, under pressure. The connecting tubes are then pinched and soldered. The milk is further sterilised by heating the cans to, say, 120° C. for 10 minutes, and placing them in water kept moving for 24 hours.—L. de K.

Blood, A New or Improved Method of Preventing the Putrefaction of. F. V. Friderichsen, Copenhagen, Denmark. Eng. Pat. 23,006, Dec. 2, 1895.

BLOOD is mixed with 10 to 50 per cent. of molasses or treacle, which will keep it from putrefying for a long time. The mixture may be administered as a nourishing cattle food, either as such or after being converted into a dry powder or meal.—L. de K.

PATENT.

Extracting Precipitated Sludge or Solids from the Bottoms of Inverted Cone-shaped Precipitating Tanks for Sewage or Waste Water, Improvements in the Means of. E. W. Ives, Derby. Eng. Pat. 22,545, Nov. 26, 1895.

INSTEAD of the apex of the inverted cone terminating in a sump, the inventor cuts off the apex, thus forming a flat surface. Upon this flat surface he places a cone, and over this a larger cone connected at its apex with a suction pipe. A space is left between the two cones for suction of the sludge from the bottom of the tank.—L. A.

(C.)—DISINFECTANTS.

PATENTS.

Washing Powders, Improvements in the Manufacture of. A. Warwick, J. Smith, and P. W. Nicolle, London. Eng. Pat. 2471, Feb. 5, 1895.

SODIUM benzoate, a powerful antiseptic and germicide, as well as a detergent and non-poisonous, is incorporated into washing powders in the proportion of from 0.25 to 1 per cent. The use of the benzoates of the other alkalis and of the alkaline earths for the same purpose is also claimed.

—L. A.

Improved Disinfecting Materials. J. B. McArthur, New-ferry, Chester. Eng. Pat. 5258, March 12, 1895.

CAMBOTIC, cresylic, and similar "acids," the oils of cloves, eucalyptus, peppermint, and similar fluids, are absorbed by means of carbon, especially certain forms of waste carbon named in the specification, also waste calcium sulphate and mixtures of the above with wood sawdust. Solutions of chlorides of calcium, zinc, or magnesium, or glycerin may be added. The mixture may be used as a powder, or may be moulded into tablets, &c. with the help of glue, paste, silicate of soda, &c.—L. A.

XIX.—PAPER, PASTEBOARD, Etc.

PATENT.

Waterproofing Paper and other Fabrics, and Apparatus therefor, and in Means for Applying Waterproof Designs thereto, Improvements in. F. Girard, Paris, France. Eng. Pat. 1518, Jan. 22, 1895.

THE paper (more especially such as is used for making cigarettes) is passed in continuous bands, while pressed down by a brush, over a "porous depositing plate," to which melted paraffin wax, stearin, &c., or varnish, is conveyed by a pump, the mechanism of which is arranged to make the rate of descent of its piston in the cylinder correspond with the rate of motion of the paper over the porous "plate." The latter is preferably composed of sheets of metal or other suitable material, fixed parallel to one another and separated by layers of felt, sponge, porous paper, &c. It is mounted so that the paper comes into contact with the edges of the sheets of metal.

Modifications of the apparatus are described in the original specification, by means of which the waterproofing agent may be applied (in pattern, &c.) to portions only of the paper.—E. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Ozone, Production of. Brimk. Zeits. anorg. Chem. 1895, 222.

WHEN oxygen is prepared in the ordinary way from KClO_3 and MnO_2 , it is found to contain ozone. If manganese peroxide be heated to 400° C., or even to redness, and oxygen gas be passed over it, ozone is also formed. The oxides of cobalt, silver, nickel, mercury, lead, chromium, uranium, and gold, act more or less in the same way. Lead peroxide heated to 400° C. yields ozone even in a stream of CO_2 .—W. S.

Mydriatic Drugs. Pharm. J. 1896, [1336], 83.

J. LAUTERER has found that the old leaves and twigs of *Duboisia myoporoides* contain hyoscyamine, the fresh young leaves, scopolamine. When the flowers commence to bud, the leaves are richest in alkaloid, containing then 0.3 per cent. In winter the amount falls to 0.03 per cent. Dry leaves contain 0.97 per cent. of alkaloid and are much stronger than belladonna leaves. *Duboisia leichardtii* is richer in alkaloid and contains chiefly amorphous scopolamine. The leaves of *Brugmansia arborea* and *B. knightii*, natives of South America acclimatised in Queensland, contain less alkaloid, consisting of two-thirds hyoscyamine, and one-third atropine.—W. S.

Ledum-Camphor, The so-called. E. Hjelt. Ber. 28, 1895, 3087—3089.

INVESTIGATIONS by the author show that ledum-camphor, from *Ledum palustre* (melting point, 104°—105° C.; boiling point, 282°—283° C.), possesses the formula $\text{C}_{15}\text{H}_{26}\text{O}$, and is isomeric with patchouli-camphor, caryophyllene alcohol, camphacol, and other sesquiterpene hydrates.

The leaves of the plant yielded 1·30 per cent. of crude oil or 0·30 per cent. of the camphor, whilst young shoots gave 0·75 per cent. crude oil or 0·28 per cent. of camphor.

—J. S.

Apo-Quinine, the Preparation and Rotatory Power of.
E. Lippmann. Ber. 1895, 28, 1971—1972.

RECENTLY, the author and Fleissner (this Journal, 1895, 677) have shown that apo-quinine—first described and prepared by Hesse—cannot be obtained in a state of purity by the process employed by its discoverer. This conclusion the author maintains,—although Hesse (Ber. 28, 1301) has since denied its correctness,—and states that by acting on quinine with hydriodic instead of hydrochloric acid, under the conditions before described, apo-quinine may be obtained free from impurities. Apo-quinine separates from ether in colourless needles, containing ether of crystallisation. The latter is slowly expelled at 110° C., and the alkaloid becomes yellow in colour, and yields a brown solution in alcohol. $[\alpha]_D^{20}$ (in alcoholic solution) = -217·1°.

The production of isomerides of quinine (in Hesse's process) is confirmed. Hitherto, the author has isolated a base, with difficulty soluble in ether, m. pt. = 170—171° C.; also the sulphate of a base ($C_{20}H_{21}N_2O_2$), m. pt. = 209—211° C.—H. T. P.

Caffeine, Synthesis of. E. Fischer and L. Ach. Ber. 28, [19], 3135—3143.

THE relation of caffeine to uric acid was first indicated by Rochleder. Subsequently Strecker traced its connection with theobromine. The common relationship of these two bases with xanthine was next established by E. Fischer, and more recently theobromine has been represented as dimethylxanthine, whilst caffeine has been regarded as trimethylxanthine. As shown in formulae given, uric acid is closely allied to xanthine, though, as Fischer points out, there are essential constitutional differences.

The structure of the carbon chain in the methyl derivatives of uric acid hitherto known, has remained unaltered, whilst hydrogen and oxygen have been removed from the alloxan nucleus. The authors have now succeeded, for the first time, in replacing both hydrogen atoms of the alloxan nucleus by methyl, and have thus obtained γ -dimethyl uric acid, which by the action of phosphorus oxychloride and pentachloride, may be converted into chlortheophylline. By reduction with hydriodic acid, chlortheophylline is converted into theophylline, chlorine being replaced by hydrogen. The yield is almost quantitative. Theophylline is contained in tea to a small extent, so small, however, that the attempt to extract it is of little use. Hence it has proved best to prepare it from caffeine, which is first converted into dimethyluramil (Ber. 28, 2475), and this by treatment with pure potassium cyanate passes almost quantitatively into dimethylpseudo-uric acid. On fusion of the latter with oxalic acid, a 60 per cent. yield of γ -dimethyluric acid is obtained, yielding 35—40 per cent. of pure theophylline, which means about 10 per cent. on the caffeine employed.

Finally, the authors succeeded in converting the theophylline obtained as above, into caffeine, by methylating according to Kossel's process.—W. S.

Lactyltropine. Pharm. Centrallh. 37, 73.

This substance has the formula—

It is prepared by heating an aqueous solution of equal parts of lactic acid, tropine, and hydrochloric acid of sp. gr. 1·12 to from 70° to 100° C. for several days on the water-bath, replacing any hydrochloric acid evaporated. The liquid is then made alkaline, and the base is removed by shaking with chloroform, the residue left after evaporating down the separated chloroform solution being purified.

Lactyltropine hydrochloride forms colourless crystals easily soluble in water or alcohol. The base itself forms bundles of acicular needles melting at 74° to 75° C.—W. S.

Triphenine. J. von Mering. Pharm. Centrallh. 37, 73.

This substance is prepared by heating *p*-phenetidine with propionic acid. It is a homologue of phenacetine, and is introduced as an antipyretic and antineuralgic. It dissolves in 2000 parts of cold water, and melts at 120° C. Seven to nine grains form a dose, said to reduce the body temperature by 2° or 3° C.—W. S.

PATENTS.

Succin Compound, and of Certain Intermediate Products therefor, The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vorm. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5135, March 11, 1895.

ORTHO-SULPHOBENZOIC ethers, $SO_2H.C_6H_4.COOR'$, are readily made by the action of alkyl-haloids on the salts of the corresponding acid, or by digesting the disodium or dipotassium salts with alcohol in the presence of hydrochloric or sulphuric acid. The corresponding chlorides, $SO_2Cl.C_6H_4.COOR'$, are readily formed by the action of phosphorus oxychloride on the sodium or potassium salts of the orthosulphobenzoic ethers. When these chlorides are treated with ammonia in excess, and the action is allowed to proceed energetically, they yield saccharin, and on acidulating the solution, the latter separates in a pure state. Mixtures of ortho- and parasulphobenzoic acids may be employed, as the sodium and potassium salts of the parasulphobenzoic ethers are much less soluble than the corresponding salts of the ortho-ethers, and so can be largely and readily eliminated; and the parasulphamine benzoic ethers are also almost insoluble in water, and so can be filtered off and the saccharin left in solution.

The patentees claim the following advantages for this process over that at present employed for making saccharin. For preparing the halogen derivative, a small quantity ($\frac{1}{2}$ mol.) of phosphorus oxychloride can be employed instead of the much larger quantity (2 mols.) of the more expensive phosphorus pentachloride now necessary for preparing the dihalogen compound. The mono-halogen ethers are more stable towards water than the dihalogen compounds, and therefore aqueous ammonia can be employed for their decomposition in place of the gaseous ammonia necessary with the dichloro-derivative.—L. T. T.

Oxygen Gas and Apparatus therefor, Improvements relating to the Production of. A. Sweetser, West Dulwich, Surrey. Eng. Pat. 12,245, June 24, 1895.

This is an apparatus intended to generate oxygen (for lime-light and other purposes) as and at the time wanted. It consists essentially of a tube (attached to suitable vessels

and a suitable receiver) through which a band, impregnated with potassium chlorate, or endless chain carrying pellets of potassium chlorate, is made to pass by means of an outside crank handle. When the tube is strongly heated the oxygen can be generated as required by moving on the band or chain by means of the handle.—L. T. T.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

PATENTS.

Photographic Plates and Films, Improvements in the Manufacture of. C. E. Oakley, Thornton Heath, Surrey. Eng. Pat. 2986, Feb. 11, 1895.

THE object of this invention is the prevention in photographic plates of the effects known as halation "by first coating the glass plate or other support with gelatin or other suitable non-sensitive material; then immersing the support in a solution of potassium permanganate or other material which will colour the gelatin and render it non-actinic by entering into the substance of same, and also harden the gelatin and render it practically insoluble, and therefore prevent it giving up its colouring matter to the sensitive emulsion; and then coating the support with a sensitive emulsion."—W. M.

Without Transfer, Images with their Half-Tints, An Improved Photographic Process, giving; and the Application of this Process to Photography in Colours. B. J. H. Mills, London. From A. and L. Lumière, Lyon-Montplaisir, France. Eng. Pat. 7188, April 8, 1895.

THE inventors have observed that bichromated glue soluble in a cold state, which does not give the half-tints when employed alone, acquires this property when insoluble substances are added to it under certain conditions. If, for example, to a 10 per cent. solution of glue there be added about 5 per cent. of bichromate of ammonia and from 5 to 10 per cent. of bromide of silver emulsion, and this preparation be spread upon a glass plate, a sensitive surface is obtained, which, when exposed under a negative, and washed with cold water, gives an image, only scarcely visible, which can be coloured suitably, the bromide of silver being dissolved out by hyposulphite of soda. With this process, it is easy to produce polychrome images, by utilising the principle of Cros and Ducois de Haumont's process, by obtaining successively upon one plate three monochrome images, red, blue, and yellow, arising from the corresponding negatives, taking care to isolate each image from the preceding one by an impermeable coating of collodion.—J. C. C.

Stripping Films for Photographic Purposes, Improvements in the Manufacture of. J. B. B. Wellington, Elstree, Herts. Eng. Pat. 10,666, May 29, 1895.

THE object of this invention is the production of flexible transparent films intended for the support of photographic emulsions, and to provide a film of insoluble gelatin which is supported during exposure upon a backing of paper, from which backing it is stripped prior to printing. The major claim is for a stripping film consisting of the combination of a paper backing, a substratum consisting of a solution of a suitable gum or resin coated thereon, a layer of gelatin upon such substratum, and a final layer of sensitive emulsion.—W. M.

XXII.—EXPLOSIVES, MATCHES, Etc.

Guncotton, Inspection of Cotton for Use in the Manufacture of. C. E. Munroe. J. Amer. Chem. Soc. 1895, 17, 783.

WEAVERS' waste, or the waste from cotton-gauze factories, is most used for the manufacture of guncotton, on account of its cheapness, and because it permits of ready handling, and also because its compactness makes it less buoyant than cotton wool.

The cotton should be free from oil, grease, &c., and from cops, tangles, &c.

The method of inspection is as follows:—1. Ocular examination for colour, cleanliness, presence of cops, knots, tangles, and foreign bodies, and for relative length and strength of fibre. 2. Odour. 3. Moisture, which is determined by drying at 100° C. to constant weight. 4. Ether extract, which is determined by subjecting a weighed sample to the action of petroleum ether (b. pt. = 50°–80° C.) in a Soxhlet extractor until the sample ceases to lose weight. The complete extraction of the oily matters generally requires several exhaustions. 5. Soda-lye extract, which is determined by boiling the weighed sample (10 grms.) for 8 hours in 104 c.c. of a solution of caustic soda (17·305 grms. of NaOH to 1 litre of water), fresh water being added from time to time to keep up the volume. Pour off the liquid, wash on a cotton filter until the wash-water gives no alkaline reaction, and then dry to constant weight. 6. Ash. Weigh out 1–1·5 gm. of the sample into a platinum crucible, pour melted paraffin upon the mass, ignite it from the top, and let it burn slowly until the flame dies out, and then ignite the residue to constant weight. 7. Rate of absorption of water. This is determined by dropping a sample of the cotton on to distilled water, and noting the time from the moment the cotton touches the water until it sinks completely below the surface. Cotton suitable for making smokeless powder should sink in two minutes. The cotton may be tested for rate of absorption, not only in its original condition, but also after treatment with ether, after drying for moisture, and after boiling with soda lye.

In 18 samples of cotton waste, the moisture varied from 3·38 to 8·40 per cent., the ether extract from 0·00 to 7·10 per cent., the soda-lye extract from 3·53 to 5·36 per cent., the ash from 0·65 to 1·79 per cent., and the rate of absorption after soda-lye extraction, from one second to over 24 hours. Experiments were made as to the absorptive capacity of the cotton, and "one 6-grm. sample of cotton was found to retain 93 grms. of water."—A. S.

PATENTS.

Explosives, Improvements in. W. D. Borland, Dartford. Eng. Pat. 6289, March 26, 1895.

THE use of insoluble or sparingly soluble chromates, such as zinc or aluminium chromate mixed with nitrocellulose, is patented. The explosive substance may be gelatinised or compressed into sheets or blocks.—W. M.

Pyrotechnic Compounds, Improvements in the Manufacture of. W. Weippenbach, Stuttgart, Germany. Eng. Pat. 24,725, Dec. 24, 1895.

THE following mixture is given; the proportions must not be materially departed from, or the result will be uncertain:—Potato starch, 250–300 parts; dextrin, 100–110; gum arabic, 50–60; powdered charcoal, 38–40; magnesium powder, 75–100; steel filings, 200 parts (may also be omitted).

The ingredients are mixed with water and then allowed to ferment, and afterwards, on standing some days, oxygen is absorbed and thus "nitrate, chlorate, and the other oxygen-containing substances hitherto employed are dispensed with, and replaced in their action by active oxygen, which during the process is itself absorbed from the atmosphere by the materials and is combined probably in the form of magnesium superoxide."—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Mercury Air Pump, Distillations with an Automatic. F. Krafft and W. A. Dyes. Ber. 28, 1895, 2583–2589.

THE automatic mercury air pump is shown in the cut. It consists of a series of concentric glass tubes G, the innermost one, *a*, Fig. 1, being a Sprengel tube 3–4 dm. long. A quantity of mercury (about 600–650 grms.) is introduced

at *o*, which is then connected with an ordinary water-pump. The mercury sinks down to *C* and then rises up between the Sprengel tube and the next tube outside it. When it reaches the level of the top of the Sprengel tube it falls through the Sprengel tube, carrying the air or gas from *P* with it. At *a* the air or gas which has been carried down by the mercury is sucked up by the water-pump between the outermost tube and the next tube within it. The mercury, on the other hand, descends past the ball-valve *E*, which closes with an excess of pressure outside and collects in the bend *m*, Fig. 3. The side tube *J A h* conveys the mercury back to the reservoir again, the action going on continuously as long as the water-pump is at work. The valve *q* is so regulated that it admits a slow current of air, filtered by passing through cotton wool between *q* and *J*, in sufficient quantity to carry up the pistons of mercury in the side tube *A*. The top of the Sprengel tube is best made in the form shown in Fig. 2 of the block. The apparatus can easily be clamped on the laboratory table by a retort stand.

The water-pump reduces the pressure in the whole apparatus to about 15 mm., and this is still further reduced to 1 mm. or less by the Sprengel pump. If water vapour be given off during the distillation, it is well to interpose a tube containing a suitable dehydrating agent between *P* and the distilling apparatus.

In order to test the pump, which is a modification of v. Babo's, the authors have made several distillations in a high vacuum, and find it very satisfactory. For example, mannite was found to distil under a pressure of 1 mm. at 276°—280°, under 2.5 mm. at 285°, and under 3—3.5 mm. at 290°—295°. The boiling points or temperatures of sublimation of dulcitol, succinic, fumaric, mesaconic, and itaconic acids were also determined at greatly reduced pressures.—J. S.

PATENTS.

Thermometers, Improvements in. J. J. Hicks, London. Eng. Pat. 1254, Feb. 27, 1895.

The improvements relate to the construction of a thermometer of the Six pattern, in which there is a combination of four parallel tubes of nearly equal length connected together and forming a continuous tube, two of the tubes being used as thermometric and two as recording tubes, and each containing a separate indicator. The series of tubes is connected with a spirit bulb and either one or a pair of expansion bulbs.—J. S.

Gases, Collecting and Analysing of, Improvements in and relating to. F. G. Waller, Delf, Holland. Eng. Pat. 1040, Jan. 16, 1895.

In the figure, A and B are two communicating vessels united by a pipe *a*, which is provided with a cock *b*. The smaller vessel B contains a float *C*, to which is attached a vertically guided rod *c*, and to this rod a siphon tube *d* is secured by a clamp *e*, so that the siphon tube may be fixed in any desired position. The one end of the siphon dips into the fluid through a hole *f* in the float *C*, and the other end *r* hangs free in the vessel *D*, provided at its lower end with a cock *n*.

The larger vessel A contains a float *p* to separate nearly the whole of the surface of the fluid from the space above it, and so prevents absorption of the gases by the fluid.

From the upper part of A, a small pipe *g* serves to convey the gases to be collected, and is provided with a soot filter *j* and a draining apparatus *g*¹ and a non-return valve *h*.

The vessel A is also provided with an inlet cock *m* and has a gauge glass *l* fitted at its side.

The apparatus is filled by pouring the liquid into the vessel B, the cocks *b* and *k* being open and *m* and *n* closed.

When filled, *k* is closed and *n* open; the siphon is then fixed on the rod *c*, so that the velocity of discharge of the liquid has the desired value, which velocity remains constant, as the siphon descends with the float C, and a volume of gas is collected at a regular speed. When sufficient gas is collected, the cock *n* is closed, the level in the cistern D rises, and the siphon stops without being emptied.

The gas may then be driven out into the analysing apparatus by closing cock *b* and forcing liquid through *m* into the vessel A.—J. C. C.

New Indicator, Luteol (Hydroxychlorodiphenylquinoxalin).
W. Autenrieth. Archiv. d. Pharmacie, 233, 43.

In contact with alkalis the solution of this substance becomes coloured intensely yellow. For its preparation 1 mol. of ethoxyphenylenediamine is heated to boiling with 1 mol. of benzyl in alcoholic solution. A crystalline precipitate of ethoxyphenylquinoxalin is obtained. This substance (m. pt. = 150° C.) is recrystallised from alcohol, and is heated in the paraffin bath at 70°–90° C. with pentachloride of phosphorus, whereby an atom of chlorine enters into combination, and phosphorus trichloride and hydrochloric acid escape.

The ethoxychlorodiphenylquinoxalin is then heated in a sealed tube with hydrochloric acid to from 180°–200° C., whereby ethylchloride is separated. The substance thus obtained is repeatedly crystallised from alcohol.

The fine, wool-like and yellow coloured needles obtained, melt at 246° C., at higher temperatures subliming without decomposition. In water the substance (Luteol) is insoluble, with difficulty soluble in cold alcohol, easily soluble in hot alcohol, and in ether. Concentrated sulphuric acid dissolves luteol, forming a red solution, from which addition of water effects separation of the unchanged luteol. It is slightly soluble in strong hydrochloric acid, completely soluble in dilute. Alkalis dissolve it easily, forming a yellow coloured solution. If 1 drop of dilute caustic soda solution be added to 1 litre of water, and of the solution 5–10 c.c. be taken, and to this liquid a few drops of alcoholic luteol solution be added, a very perceptible yellow tint is produced. The delicacy is considerably greater than in the colour reactions produced by litmus or phenolphthalein. Luteol has the advantage over phenolphthalein that it can be used with ammonia, and over litmus in that it shows a very sharp indication of permanent tint, without any production of intermediate shade, as with litmus. A luteol solution of convenient strength is one of 1 grm. in 300 c.c. of pure alcohol.—W. S.

INORGANIC CHEMISTRY.—QUALITATIVE.

Hydrogen Peroxide, Reagents for the Detection of. L. I. von Nagy Hosva. Ber. 1895, 28, 2029–2031.

Bach (this Journal, 1895, 399–400 and 597) has described a very sensitive colour reaction which hydrogen peroxide yields with a dilute solution of aniline and potassium bichromate. The author finds that other aromatic amines furnish similar results. Adopting Bach's *modus operandi*, the following colorations were obtained with a solution of hydrogen peroxide containing 1 per 1 to 2 millions:—Dimethylaniline, yellow; sulphanilic acid, violet-red; *o*-toluidine, yellow-green, not characteristic; *p*-toluidine, copper-red; tolylenediamine, pale rose-red; xylydine, yellowish-pink, changing to reddish-violet; naphthylamine, reagent decolorised, then changed to bluish-violet. Of these, dimethylaniline is the most sensitive, giving a distinct reaction in 5 minutes with a peroxide solution containing only 1:5,000,000. It must be noted, however, that dimethylaniline, tolylenediamine, and naphthylamine cannot be relied upon in presence of traces of nitrous acid. Moreover, ozone yields with all the above reagents colorations very similar to those furnished by hydrogen peroxide.

—H. T. P.

Tellurium Salts, New Reactions of. C. Whitehead.
J. Amer. Chem. Soc. 17, 849.

THE addition of an ammonium salt in solution to a solution of sodium or potassium tellurite produces a white precipitate, which becomes granular on boiling; a small amount of a substance, probably tellurium, that may be precipitated by sulphur dioxide, being left in solution. The author is engaged in examining this substance. The reaction may be expressed thus:—

On passing hydrogen telluride for some time into a solution of tellurium chloride, tellurium and tellurides are precipitated, but the solution still contains tellurium. The equation is: $\text{TeCl}_4 + 2\text{TeH}_2 = 3\text{Te} + 4\text{HCl}$. Potassium ferrocyanide added to tellurium chloride gives no change at first, but after a few hours much Prussian blue is formed.

Aluminium Telluride.—Aluminium combines directly with tellurium with explosive violence, forming a difficultly fusible, chocolate-coloured compound, having the formula Al_2Te_3 . It is so brittle that it may be ground to powder; it is of constant composition, and forms hydrogen telluride in moist air, and reacts rapidly with water according to the equation $\text{Al}_2\text{Te}_3 + 3\text{H}_2\text{O} = \text{Al}_2\text{O}_3 + 3\text{TeH}_2$. The hydrogen telluride is, however, much more easily oxidised than hydrogen sulphide, and if unboiled water be used in the above experiment, fully one-half of the tellurium will remain as metal: $\text{TeH}_2 + \text{O} = \text{H}_2\text{O} + \text{Te}$. The aluminium compound gives no reaction with 95 per cent. alcohol even on boiling, and, being less oxidisable than alkaline tellurides, is the best source from which to prepare the organic salts.

Electrolytic Separation from Copper.—Even the feeblest current deposits tellurium, but not in the reguline state. To separate it from copper, the solution is mixed with an excess of sodium hydroxide and about 3 grms. of potassium cyanide per grm. of copper present. A current, such as is used for depositing copper, will in 12 hours throw down all the tellurium from this solution as a black non-adhesive precipitate; it is then filtered off and weighed, either as Te or as TeO_2 , and the solution is acidified with sulphuric acid and electrolysed for copper. With the right amount of cyanide, and if the current be not passed for too long, the tellurium is quite free from copper; and, given sufficient current-strength, no tellurium will adhere to the cathode.

—W. G. M.

Nitrous Acid in Mercurous Nitrate, and Nitrites, Test for. K. Gorter. Apoth. Zeit. 11, 95.

THE author points out that Denigés' test with mercurous acetate is practically identical with that of Plugge, devised in 1875. He showed that mercurous nitrate, when free from nitrous acid, gives no red tint with phenol, but that the minutest trace produces the red coloration.—W. S.

Nitrates in Water, Detection of. Alessandri and Guassini. Bollet. Chim. Pharm. 1895, 490.

THE evaporated residue of the water, whilst warm, is mixed with a few drops of a solution of carboic acid in strong hydrochloric acid. On heating, an intense reddish-violet coloration is produced, when the smallest trace of nitrates is present. Addition of ammonia changes the colour to emerald green. Water with very minute traces of nitrates gives the violet tint, a green tint being produced when the trace becomes almost a vanishing quantity.—W. S.

INORGANIC CHEMISTRY.—QUANTITATIVE.

Phosphoric Acid, Estimation of, by Titration. De Molinari. Bull. de l'Assoc. Belge des Chimistes, 9, 280–282.

THE Pemberton method, whilst applicable in its original form to slags and ordinary phosphates, gives results that are too high when free sulphuric acid or sulphates are present. In such cases it becomes necessary to effect a precipitation of the acid by barium chloride or to add to the solution under examination an equal bulk of alkaline ammonium citrate (Petermann's formula) before performing the titration. Directions are given for the determination of

(1) the phosphoric acid soluble in water, (2) total phosphoric acid in superphosphate, (3) that soluble in water and alkaline ammonium citrate (in mixed manures), (4) that soluble in acid ammonium citrate.—C. S.

Silver Ores [Rich], *Notes on the Assay of*. E. H. Miller and C. H. Fulton. *Sch. of Mines Quart.* 1896, **17**, 160—170.

A COMPARISON is made between the crucible and the scorification assays as applied to two ores, one being a cerussite, containing about 2,000 oz. of silver and 0.28 oz. of gold per ton, with 28 per cent. of lead; the other being a rich silver sulphide, with 17,000 oz. of silver and 240 oz. of gold per ton. In each case the amounts of precious metal left in the slag and in the cupel were determined separately, and the residues left in the second (cleaned) slags and the second cupels were determined together, these forming the "second correction" noted below. In the crucible, an increase in the proportion of litharge adds very slightly to the silver in the slag; and the weight of silver obtained from the lead button increases regularly with the size of that button to a maximum of 28 grms., and then diminishes owing to the greater loss of precious metal during the subsequent scorification and cupellation. The weight of silver recovered from the cupel is usually greater than that from the crucible slag, increasing regularly, but not in direct proportion, with the size of the button. Feathers on the cupel are not in all cases a correct indication of temperature, but depend to some extent on the position of the cupel in the muffle. The best method of assaying must be worked out for each ore, but the following conclusions appear to be warranted:—(1.) The crucible assay is the best for all gold ores, and for silver in pure ores, particularly in those which have a basic gangue. (2.) Uncorrected scorification assays are higher than uncorrected crucible assays for impure materials (sulphides, &c.) carrying silver. (3.) The corrected crucible assay is usually slightly higher than the corrected scorification assay, because of the loss of silver by volatilisation during scorification. The amount of gold recovered in correcting either assay is very small, but is greatest in the scorification process. The actual loss of gold during the cupellation of the richer ore was found to range from 0.00075 to 0.00095 mgrm. per grm. of lead button cupelled, the loss of silver being often a thousand times as great as this. The average results of the assays are shown in a table.

Other investigators working in the same field have obtained similar results. Mason and Bowman found a loss of silver in scorification equal to 0.55 per cent., and of gold 0.574 per cent., whilst in cupellation, the losses were 1.99 and 0.295 per cent. respectively (this *Journal*, 1895, **14**, 39). Dewey found a correction of 2.6 per cent. necessary for lead carbonate carrying from 100 to 500 oz. of silver, and of 1.26 per cent. for scorification assays of precipitated sulphides running 17,500 oz. per ton (this *Journal*, 1895, **14**, 301). Steinfeldt for similar materials obtained the numbers 2.9 and 1.2 per cent., but these omit the second correction given by the author. Furman gives the average losses in the crucible assay as 2.58 per cent. for silver and 0.30 per cent. for gold. Finally Rose has shown that of the gold lost, 82 per cent. is absorbed by the cupel.

—W. G. M.

Alloys of Lead, Tin, Antimony, and Arsenic, Analysis of. L. Andrews. *J. Amer. Chem. Soc.* 1895, **17**, 869—873.

First Method.—About 0.5 grm. of the alloy in the form of turnings, is placed in a porcelain boat within a combustion tube, in which the tube being covered with an asbestos tent, it may be heated by an argand burner to 210° C. During this time fuming hydrochloric acid is allowed to flow through a capillary tube into strong sulphuric acid contained in a flask; in this way, a steady and slow stream of hydrochloric acid gas is generated and passed through a second flask containing 10 c.c. of nitric acid (1.5 sp. gr.) and thence into the combustion tube. The gaseous products of the reaction with the alloy, traverse a well-cooled Volhard absorption flask containing potassium bromide solution. After two hours the action is complete; the

snow-white residue in the boat contains all the lead, and is quite soluble in boiling water; the lead is weighed as sulphate. The sublimate in the unheated part of the combustion tube is rinsed with hydrochloric acid into the absorption flask, which then contains the antimony, arsenic, and tin. The arsenic is removed by Gooch's method of distillation, and the tin and antimony are then separated according to Carnot's process (this *Journal*, 1892, 941) by boiling the solution, containing an oxalate, free oxalic acid, and much ammonium chloride, with sodium thiosulphate. Besides observing the precautions recommended by Carnot, it is necessary to boil the solution violently until one-fourth is evaporated, and to ensure that the acid is finally in excess in regard to thiosulphate.

Second Method.—When antifriction or type metals are treated with hydrobromic acid a residue of pure antimony is left, but a small proportion of antimony passes into solution owing to oxidation. By adding a reducing agent, such as hydriodic acid, the whole of the antimony will be left in the residue. 1 grm. of the metal in turnings is therefore boiled for an hour with hydrochloric acid (1.1 sp. gr.) and 1 grm. of potassium iodide. The residual dark grey powder of antimony is filtered boiling, washed with boiling water until free from lead iodide, dried, mixed with sulphur, and gently ignited in a current of carbon dioxide. If the antimony be weighed direct, the results will be about 0.7 per cent. too high, in consequence of the retention of water or hydrogen by the metal. In igniting antimony sulphide in this manner, the required temperature of 400° C. is most conveniently obtained by supporting the tube over an Argand burner, and there covering it with a tent of asbestos or sheet-iron. This method of heating is recommended as giving absolute control over a wide range of temperatures, and as being safer than direct heating by means of a Bunsen burner.

Results by both processes, as quoted, were excellent.

—W. G. M.

Lead, The Volumetric Determination of. A. S. Cushman and J. Hayes-Campbell. *J. Amer. Chem. Soc.* 1895, **17**, 901—904.

THE authors recommend a modification of the Schwartz process. 1 grm. of the ore is digested in a porcelain dish with 15 c.c. of a mixture of 2 parts of nitric with 1 of sulphuric acid until decomposition is complete. 10 c.c. more sulphuric acid is added, and the liquid is evaporated until it fumes freely. It is then cooled, and 10 c.c. of dilute sulphuric acid (1:10) and 40 c.c. of water are added successively. The mixture is heated to boiling, filtered, and washed with dilute (1:10) sulphuric acid by decantation, getting as little as possible of the precipitate upon the filter. The residue in the dish is mixed with 20 c.c. of strong ammonia, and the mixture is then slightly acidified with acetic acid, and boiled until the lead sulphate is dissolved, when it is poured over the filter, which must have been previously moistened with ammonia. The filter is washed with dilute ammonium acetate solution, and then with hot water. After cooling the filtrate, an excess of standard bichromate solution is added from a burette, until the precipitate settles rapidly and the supernatant liquid is yellow. The precipitate is allowed to subside, and after a few minutes it is filtered, if possible under pressure, and washed; and the excess of bichromate is titrated back with standard ammonio-ferrous sulphate solution. The whole process can be conducted in 30 minutes. In the absence of bismuth and antimony, nitric acid alone may be used in attacking the ore; the acid solution is then mixed with an excess of ammonia, and afterwards with acetic acid, to dissolve any lead sulphate that may have been formed. The additions of bichromate and ferrous salt are made as before. The time required is thus materially shortened. The standard ferrous solution may be preserved for a long time unchanged in a corked bottle with a siphon and pinchcock, and with a thin layer of paraffin oil resting on the surface of the liquid. The results are a trifle low, averaging about 99.6 per cent. of the true number.

—W. G. M.

Mercury in Cinnabar, Electrolytic Method for Determination of. W. B. Rising and V. Lenher. *J. Amer. Chem. Soc.* 1896, **18**, 96—98.

THE mercuric sulphide is treated with hydrobromic acid in which it dissolves very readily; the solution is nearly neutralised with caustic potash, pure potassium cyanide added in sufficient excess to redissolve the precipitate which is at first formed, and the solution is electrolysed by means of a weak current; the operation is carried out in a platinum dish which acts as the negative electrode and on this the mercury becomes deposited. The advantage of hydrobromic acid over aqua regia, is that it dissolves cinnabar at low temperatures so that no loss of mercury by volatilisation occurs. Results are given showing the accuracy attainable.—A. K. M.

Sulphur in Refined Copper, Estimation of. G. L. Heath. *J. Amer. Chem. Soc.* 1895, **17**, 814.

THE author criticises the existing methods for the estimation of sulphur in copper. The method of R. Fresenius (*Zeits. Anal. Chem.* **13**, 223), in which the sulphur is precipitated by barium nitrate from a slightly acid solution of copper nitrate, is inaccurate on account of the solubility of barium sulphate in copper nitrate solution.

There are two or three possible sources of error in W. Lampe's method, which consists in passing pure dry chlorine gas over the heated copper, and absorbing the sulphuric acid evolved in water saturated with chlorine. The sources of error are:—1. The existence of the sulphur in different forms. 2. The incomplete removal of oxygen and other impurities from the chlorine gas. 3. The formation of a layer of melted chloride, which may prevent the complete oxidation of the sulphur.

The author made a series of experiments to test the accuracy of H. J. Phillip's method (*Chem. New.* **62**), in which the sulphur is precipitated from a hydrochloric acid solution, after removing all the nitric acid by repeated evaporation. He obtained the following results:—With 0.1 gm. of copper present and the volume of the solution not exceeding 100 c.c., the barium sulphate is completely precipitated whether the solution is strongly acidified or not. With 2.5 grms. of copper and the volume of the solution increased to 350 c.c., the barium sulphate is completely precipitated in 72 hours. If the copper be increased to 10 grms., the precipitation is very slow, and in the strongly acidified solutions at least, is not complete. Cupric chloride retards the precipitation of the barium sulphate, especially when strongly acidified. The following is an accurate method devised by the author and L. M. Norton and improved by the former.

Enough copper is taken to yield a weighable amount of barium sulphate, generally about 10 grms.

Dissolve the copper in a mixture of 60 c.c. of nitric acid (1.42 sp. gr.) and 15 c.c. of hydrochloric acid (1.20 sp. gr.), in a large beaker over an alcohol flame. Evaporate nearly to dryness, add 50 c.c. of strong nitric acid and evaporate again. Repeat this operation and then add 300 c.c. of water and a little nitric acid, if a trace of basic salt remain undissolved. The addition of hydrochloric acid and subsequent evaporation with nitric acid may be dispensed with if experiment shows that nitric acid alone will oxidise all the sulphur in the material operated upon.

Filter into a 700 c.c. beaker and make up to 600 c.c. with distilled water. Introduce two electrodes, a large cone or a sheet of platinum 4 by 5 inches as the negative, and a piece of platinum wire or foil as the positive. Cover the beaker with glass and connect the electrodes, preferably with an Edison incandescent lamp circuit. When the liquid is colourless or nearly so, remove the electrodes and wash them with distilled water, allowing the washings to run into the main solution. Pour off the clear liquid from any bits of spongy copper, washing these on a small filter. Add 0.1 gm. of pure sodium carbonate and evaporate to dryness over an alcohol flame, being careful to avoid loss by spitting. Heat strongly and then allow to cool. Add to the residue 10 c.c. of strong hydrochloric acid and 5 c.c. of water and evaporate to dryness on the water-bath. Repeat this and then dissolve in 50 c.c. of water and 1 c.c. of strong hydrochloric acid, filter and

wash with hot water. Heat the solution of sodium sulphate to boiling, precipitate with a slight excess of barium chloride and allow to stand for 24 hours, or, if the results be desired at once, keep the liquid at a temperature of not less than 75 °C. for three hours. If lead be present, it will mostly remain in solution, and be deposited on the platinum, but if any lead sulphate remain on the filters, they must be boiled with a solution of pure sodium carbonate, the solution filtered, and the sulphuric acid recovered as barium sulphate.

The acids and distilled water used in the analysis should be measured and a blank analysis made.—A. S.

Pig-Iron, Determination of Graphite in. P. W. Shimer. *J. Amer. Chem. Soc.* 1895, **17**, 873—876.

THE estimation of graphite by the treatment of iron with hydrochloric acid is known to give higher results than when nitric acid is used, and the former process is therefore generally preferred. The difference is now found to be due to titanium carbide, which is insoluble in hydrochloric or sulphuric, but soluble in nitric acid. Other insoluble carbides, for example, that of vanadium, may also contribute to the result. In a pig-iron, containing 0.399 per cent. of titanium, and therefore 0.1 per cent. of carbon in the form of TiC, the graphite as determined by nitric acid was 3.206, and by hydrochloric acid 3.327 per cent. The hydrochloric residue from this iron, boiled with nitric acid (1.2 sp. gr.) for an hour, lost so much in weight that the final result agreed with that obtained by direct solution of the iron in nitric acid. The author has never met with a sample of pig-iron free from titanium, and usually finds from 0.05 to 0.40 per cent. of this element, which would therefore increase the apparent percentage of graphite, as determined by hydrochloric acid, by from 0.013 to 0.1 per cent. In irons which have a coarsely crystalline fracture, the cubical crystals of titanium carbide will always be found. It is therefore desirable to make determinations of the total carbon, of the true graphite by the nitric acid method, and of the carbon insoluble in hydrochloric acid; which would show the amount of graphite, of carbon combined with iron and manganese, soluble in hydrochloric acid, and of carbon in the form of carbides insoluble in that acid. In high-silicon low-sulphur titaniferous irons the percentage of insoluble may exceed that of the soluble carbides. If the insoluble carbon be present as titanium carbide disseminated in crystals through the metal, it probably has less influence upon the hardness of the pig-iron than if it be diffused as iron and manganese carbides, and it is therefore probably better that it should be reported as graphite than as combined carbon; and hydrochloric acid would in this case be the more satisfactory solvent to employ alone. But in any case the method employed should be stated.—W. G. M.

Cast-Iron, White; The Evolution Method for the Determination of Sulphur in. F. C. Phillips. *J. Amer. Chem. Soc.* 1895, **17**, 891—900.

IT has long been recognised that the evolution method gives low results with cast-iron samples that contain much combined carbon. Experiments with an iron containing 0.17 per cent. of sulphur, as found by the aqua regia method, are described at length, the object being to find and to obviate the sources of error. On treating the iron with hydrochloric acid and absorbing the gases in bromine water, an oil condensed in the absorption flask. This oil was separated, and found by ignition in nitrous oxide to contain sulphur; this sulphur thus resisted oxidation by bromine, and heating with concentrated nitric acid for two hours also failed to convert it into sulphuric acid; but evaporation with barium nitrate, followed by ignition, led to the formation of barium sulphate. The oil, however, was not a pure sulphur compound, it gave acetylene on treatment with alcoholic potash, and probably, therefore, contained ethylene dibromide. Drops of oil left in the evolution flask also gave evidence of containing sulphur, whilst the silica remaining in the flask, when extracted with boiling alcohol and boiling chloroform, successively, as in the process of fat extraction, yielded a yellow oil, which was left on distilling off the solvent, and contained sulphur.

The siliceous residue, after extraction, was free from sulphur. Finally the ferrous chloride left in the flask yielded a sulphur compound to chloroform by agitation. There were thus obtained from 100 parts of the iron—in the oil from the bromine solution, 0.008; in the oil rinsed from the evolution flask, 0.010; in the siliceous residue, 0.013; and in the ferrous chloride, 0.009; or 0.04 parts in all of sulphur; and this was exclusive of any contained in more volatile compounds lost in evaporation. By passing the gases from the dissolving iron through alkaline lead acetate, in addition to the black lead sulphide, there was produced a yellow precipitate soluble in excess of the liquid, which gave unmistakable evidence of the presence of methyl hydrosulphide; on passing the gases through alcoholic mercuric chloride, a white precipitate was formed which had the properties of $(\text{CH}_3)_2\text{S} \cdot \text{HgCl}_2$, so that methyl sulphide was probably present also.

Attempts were made to obtain satisfactory analytical results by oxidising the gases by combustion, but, for various reasons given, the experiments were unsuccessful. The following process was ultimately devised, and was found to give results which accorded well with those obtained by the *aqua regia* method. The iron was dissolved in hydrochloric acid (sp. gr. 1.12) with a slow stream of carbon dioxide passing through the flask, heat being applied as the action became slower; the mixed gases were led through a porcelain tube heated to dull redness, whereby methyl sulphide and hydrosulphide would be converted into H_2S . The delivery tube from the flask projects so far into the porcelain tube that it allows any drops of condensed liquid to fall upon a roll of platinum foil 8 ins. long, placed within the porcelain tube for the purpose (to minimise risk of fracture). The gases then pass to a nitrogen flask containing a hydrochloric acid solution of bromine as an absorbent, and thence to the bottom of an 8-litre flask containing a little of the same solution to retain the last traces of sulphuric acid, which would otherwise escape. The flask containing the ferrous chloride must be kept gently boiling for two hours, a slow current of CO_2 passing all the time, to ensure the removal of all the oily particles. Two samples of cast-iron gave the following results as the mean of several sulphur determinations in each case:—By the *aqua regia* method, 0.160 and 0.171; by the old evolution method, 0.052 and 0.094; and by the author's method, 0.099 and 0.180 per cent. respectively.—W. G. M.

Manganese and Tin, Quantitative Electrolytic Analysis
of. C. Engels. Ber. 1896, 23, 3182–3189.

Manganese.—The deposition of an adhesive coating of manganese peroxide upon a roughened anode surface has not hitherto been effected successfully with more than 0.05 gm. of manganese present. With suitable proportions of ammonium acetate, hydrogen peroxide, and ammonia a greater weight of manganese may be determined, but the best results are obtained in the presence of chromium oxide, whereby 0.7 gm. of manganese peroxide may be separated in a perfectly adhesive form in the space of an hour and a quarter. A dish with a matt surface must be employed, in it the manganese salt is dissolved in about 50 c.c. of water, 10 grms. of ammonium acetate, and from $1\frac{1}{2}$ to 2 grms. of chrome alum are added, and then after making up the solution to 150 c.c., it is heated to 80°C . and electrolysed with a current of $\text{ND}_{100} = 0.6$ to 1 ampère, obtained from four accumulators joined in series. The current strength may vary within wide limits, but an increase beyond $\text{ND}_{100} = 0.9$ to 1 ampère leads to no saving of time. After electrolysing for an hour, the addition of water to the solution should show that no further deposit is coming down. The fall of potential between the electrodes ranges between 3 and 4 volts. To ensure the adhesion of the deposit, the dish must be perfectly clean, and the temperature during the deposition must exceed 80°C . The quantities above given are calculated for use with 0.2 to 0.25 gm. of manganese, and they must be increased or diminished according as the weight of manganese is greater or less than this, provided that the extreme limits, of 5 and 15 grms. for ammonium acetate, and 1 and 3 grms. for chrome

alum are not passed. The manganese must be present as sulphate, and an addition of 5 c.c. of 50 per cent. acetic acid is not prejudicial, but the use of chlorides destroys the adhesion of the oxide. After the completion of precipitation the current is discontinued, and the deposit is washed several times with water and alcohol, and dried. Although pulverulent, the particles of the peroxide should be so cohesive and adhesive that even a powerful jet of water should fail to detach any, and only rubbing (as with the finger) will suffice to dislodge them. The dish with the deposit is then heated more strongly until the change of colour to a uniform dark or light red-brown, indicates conversion into manganous-manganic oxide. The original manganese peroxide retains traces of chromic acid with great obstinacy, but the latter may be completely removed, without loosening the deposit, by washing it *after ignition* several times with cold water and alcohol. The dish, after drying, is then ignited for a moment in the blowpipe flame, cooled, and weighed. Repeated reheating is unnecessary. The dish always loses 1 mg. in weight, and this occurs during electrolysis, the final weight of the cleansed dish must therefore be deducted instead of the initial weight. During electrolysis the chromium trioxide is converted more or less completely into chromic acid, and the colour of the liquid changes accordingly from green to yellow; it is probable therefore that, by absorbing the nascent oxygen at the anode, the chromium salt prevents the formation of gas bubbles and favours the adhesion of the deposit. At the same time it appears to reduce a portion of the manganese peroxide, as the precipitated oxide usually contains only from 75 to 95 per cent. of that substance. As another reducing agent, alcohol, in the proportion of 5 to 10 c.c., with 10 grms. of ammonium acetate, and 0.2 gm. of manganese gave a good result when electrolysed at a temperature of $70^\circ\text{--}80^\circ\text{C}$. With larger quantities of manganese the deposit scaled to some extent, but only in large flakes, which could be washed in the dish easily, and without loss. The chrome addition gave similar results in this respect. The effect of 0.2 to 0.3 gm. of hydroxylamine sulphate, when added to the solution, was similar to that of urea, but 1 to 2 grms. of the hydroxylamine sulphate or chloride entirely prevented precipitation. Similar proportions of potassium nitrite and hydrogen peroxide also stopped the deposition, until they became decomposed by the action of the current. The hydroxylamine salt appears to be regenerated during electrolysis, and the quantity named suffices to retain the manganese in solution during a treatment of several hours, and since it exerts no similar influence on the deposition of lead peroxide, its use enables a quantitative separation of manganese and lead to be made. Other separations, with the help of hydroxylamine, are in progress. The results obtained by the chrome alum and the alcohol methods are accurate under the conditions named above, but the use of greater weights than 0.3 to 0.4 gm. of manganese is contra-indicated.

Tin.—Hydroxylamine salts have the same effect of preventing deposition of peroxide upon the anode in tin solutions that they have in the case of manganese. Working in the cold a low current density ($\text{ND}_{100} = 0.2$ ampère) and a high voltage (7 volts) is desirable. Certain other salts, may with advantage be added; and the process finally recommended as applied to the analysis of pure ammonium-stannic chloride, is as follows:—About 1 gm. of the double salt is dissolved, and any slight turbidity is cleared up by the addition of a few c.c. of oxalic acid solution; about 0.3 to 0.5 gm. of hydroxylamine sulphate, 2 grms. of ammonium acetate, and 2 grms. of tartaric acid are then introduced, the solution is made up to 150 c.c., heated to $60^\circ\text{--}70^\circ\text{C}$., and electrolysed at that temperature with a current of $\text{ND}_{100} = 0.9$ to 1.0 ampère and 4 to 5 volts. Evaporation must be checked by means of a cover-glass, or a dark ring will form around the top of the deposit. With 1 gm. of the double salt, the tin should be completely deposited in three hours as a brilliant white and lustrous deposit. Using the same solution cold, with a current of 7 volts and $\text{ND}_{100} = 0.15$ ampère, the deposit had not such a brilliant appearance, but the quantitative results were equally satisfactory.—W. G. M.

Manganese, Volumetric Estimation of. G. Auchy.J. Amer. Chem. Soc. 1895, **17**, 943—947.

The author's experience with Williams' method of estimating manganese in steel, leads him to conclude that it usually but not always, gives accurate results. Attention is drawn to the following precautions in the practice of Volhard's method (this Journal, 1884, **3**, 522). 1. Too great an excess of sulphuric acid should be avoided during the evaporation to dryness. 2. The dry mass after cooling a minute or two should be taken up with hot water, for if cold water be used, on subsequent boiling red ferric sulphate separates, containing a considerable amount of manganese which remains insoluble. 3. It is essential that too large a quantity of zinc oxide should not be used, as it will separate when the solution is heated, and retard or completely prevent the deposition of manganese dioxide according to whether the steel is high or low in manganese, and thus render the observation of the end of the titration impossible. Before the zinc oxide is added the solution should be of small bulk, and nearly neutralised with sodium carbonate. 4. During titration the reddish colour produced by the permanganate should be completely changed into a clear yellow by shaking, before adding more, and at the end the liquid must be permanently rose-coloured after a dozen shakings.—J. L. B.

Molybdenum, Estimation of. C. Friedheim and H. Euler. Ber. 1895, **28**, 2061—2067.

I. Gravimetric Methods.—The estimation of molybdenum and its separation from the alkali metals has recently been effected by heating the molybdenum salt to 440° C. in a current of dry hydrochloric acid gas. An alkaline chloride remains behind and the molybdenum distils over in the form of the acid chloride $\text{Mo}(\text{OH})_2\text{OCl}_2$ (or $\text{MoO}_3 \cdot 2\text{HCl}$) which is condensed by passing into water. The solution, on evaporation, yields molybdenum trioxide which is weighed.

This method is, unfortunately, not always applicable, Peckard having shown that, in the presence of ammonium salts, or in combination with a metal yielding a readily fusible chloride, the molybdenum is not completely volatilised as acid chloride. In such cases the older analytical methods must be employed.

The authors of the present paper have found that the oxidation of the sulphide is best effected by direct heating, providing the following mode of procedure be followed.

The sulphide, precipitated from ammonium sulphide solution by means of dilute hydrochloric acid or from hydrochloric acid solution by the action of sulphuretted hydrogen, is allowed to settle and is then filtered. It is first washed with water containing a little sulphuric acid, and finally, to remove the acid, with aqueous alcohol. The moist filter paper and contents are now placed in a weighed porcelain crucible and dried at about 100° C. The covered crucible is next cautiously heated until hydrocarbons cease to be evolved, and, after removal of the lid, the carbon adhering to the crucible wall is burnt at as low a temperature as possible. The temperature is then carefully raised to convert the sulphide into oxide, this has been done when sulphurous anhydride ceases to come off. The trioxide is next dissolved in ammonia solution and filtered, and the filtrate evaporated to dryness. The residue is gently ignited until the ammonia has disappeared and the colour has become a uniform yellow; it is then weighed as trioxide.

The method gives good results and is applicable to the analysis of phosphorus and arsenic molybdates, &c.

II. Volumetric Methods.—The authors have found that, observing due precautions, the determination is best made in a Bunsen apparatus. They proceed as follows:—

0.2—0.3 gm. of the molybdate is placed in the distilling flask of a Bunsen's apparatus with 0.5—0.75 gm. of potassium iodide and sufficient hydrochloric acid (sp. gr. 1.12) is added to fill the flask two-thirds full. The apparatus is then connected up and the contents of the flask gradually warmed and only raised to boiling temperature when the conducting tube is filled, as much as possible, with iodine vapours and danger of the condensing liquid flowing back begins. When the iodine is completely evolved, i.e., when no more red vapours are visible and the solution is of a light

green colour, the distillation is interrupted, and the iodine absorbed in the condensing flask in potassium iodide solution, titrated with sodium thiosulphate.

Care must be taken not to heat too rapidly at the start, or hydriodic acid may be evolved, and become decomposed by the air in the neck of the apparatus. The method cannot be used for molybdates of such bases as iron, which themselves separate from KI.—J. T. C.

Molybdenum Trioxide and Vanadium Pentoxide, Estimation of, in the Presence of each other. C. Friedheim and H. Euler. Ber. 1895, **28**, 2067—2073.

The method depends upon the fact that whereas molybdenum trioxide oxidises hydriodic acid, with liberation of iodine, it is without action on hydrobromic acid, whilst, according to Holverscheidt, the latter acid is readily acted upon by vanadium pentoxide, which undergoes quantitative reduction to the tetroxide. The following reactions are therefore involved:—

The authors show that hydrochloric acid is not sufficient to ensure complete reaction between V_2O_5 and KI, and that the presence of some other acid, such as phosphoric acid, is necessary; and further, that the reduction of V_2O_5 by successive treatment with hydrobromic and hydriodic acids proceeds in two equal stages.

The following mode of procedure for the separation of molybdenum and vanadium is then given:—

The substance is decomposed by distilling in a Bunsen's apparatus with potassium bromide and concentrated hydrochloric acid, and the iodine, liberated by passing the evolved bromine into KI solution, estimated with $\frac{1}{50}$ normal thiosulphate solution. To the cooled contents of the distilling flask about 1 gm. of solid potassium iodide and 1—2 c.c. syrupy phosphoric acid are added, and the distillation continued till the red colour, due to the distilled iodine vapours, has vanished. The iodine set free is titrated with thiosulphate, and by subtracting the amount of thiosulphate first used from the value now obtained, the number of c.c.'s due to molybdenum compounds, is found.

The authors state that this method (dependent on the varying stabilities of the halogen acids towards different oxidising agents) is capable of extended application.

—J. T. C.

Silicates, Decomposition of, by Boric Acid. P. Jaunisch. Ber. 28, 1895, 2822—2823.

In this preliminary note the author states that he has successfully decomposed silicates by fusion with dried boric acid. One gm. of the finely-powdered silicate is mixed with 5—6 grms. of the dried acid and strongly ignited for 15—20 minutes. The fused mass is then either completely soluble in hot water and alcohol, or only leaves a precipitate of silica behind. The solution is evaporated to dryness, the excess of boric acid expelled by repeatedly evaporating with strong hydrochloric acid and methyl alcohol, and the analysis is then conducted in the usual way.—J. S.

Potable Waters, Determination of Nitrites in. A. H. Gill and H. A. Richardson. J. Amer. Chem. Soc. 1896, **18**, 21—23.

The authors have tested a large number of waters for nitrites, both by Trommsdorff's iodo-zinc starch method and by Griess's α -naphthylamine test, and they find very marked discrepancies in the results obtained by the two methods when applied to peaty waters. For instance, in cases where the Griess test showed as much as 0.0010 part of nitrogen (as N_2O_5) per 100,000, the Trommsdorff method gave no blue coloration. This difficulty can be overcome and concordant results obtained if the water be decolorised by agitation with "milk of alumina" and then filtered. This milk of alumina is prepared by precipitating a boiling solution of 125 grms. of potash alum per litre, with ammonia, letting the alumina settle, and washing by decantation. Even with Griess's test it is found advantageous to decolorise peaty waters before applying the test.

The authors regard 0.0001 part of nitrogen (as N_2O_5) in 100,000 as the limit of the naphthylamine test, whilst the iodo-zinc starch method is incapable of indicating less than 0.0002 part of nitrogen per 100,000.—A. K. M.

Zinc, Sulphur and Carbon in. R. Funk. Ber. 1896, 28, 3129.

See under X, page 200.

ORGANIC CHEMISTRY.—QUALITATIVE.

Primary and Secondary Nitro Compounds, A Delicate Reaction for. M. Konowalow. Ber. 28, 1850—1852.

VICTOR MEYER'S reaction for nitro compounds is only satisfactory for those of low molecular weight, whereas their detection is a simple matter by the following reaction, depending upon the red colour of a ferrie salt formed. A small quantity of the substance is shaken with sodium alcoholate and the salt is extracted with water, the solution being subsequently mixed with a small quantity of ether or benzene. Ferrie chloride is then added to the mixture, which is vigorously agitated after each addition. A red coloration indicates the presence of a nitro compound. The colour due to the formation of a ferrie salt is more marked the higher the molecular weight of the compound, owing to the insolubility in water of the higher homologues and their greater solubility in ether, benzene, &c. As an example of the delicacy of the reaction, 1 part of α -phenyl-nitropropane ($C_6H_5CH_2CH_2NO_2$) in 14,000 parts of benzene gave a distinct coloration with ferrie chloride after standing about one hour in contact with the sodium alcoholate. The reaction is not given by isopropyl nor by amyl nitrite.

—T. A. L.

Sesame Oil, The Characteristic Reaction of. J. Wauters. Bull. de l'As.-oc. Belge des Chimistes, 9, 275—280.

REFERRING to the modification in the Baudouin reaction introduced by Villavecchia and Fabris (this Journal, 1894, 69), the author states that it may be rendered still more delicate by simply pouring the oil to be tested into the tube containing the reagents. The coloration forms at the point of contact, and is not masked by the yellow colour occasioned by rancid olive oil.

In testing butter, the latter should first be melted at 40 to 45°, which prevents setting from contact with the cold acid. As low as $\frac{1}{4}$ per cent. of sesame oil is detected by this reaction in fresh butter, but rancidity may cause sufficient brownish tinge to hide the rose coloration when the sesame oil is merely present in minute quantity.

The same reaction may be employed to detect the presence of furfural in distillation products by agitating 10 c.c. of sesame oil with an equal quantity of HCl and then adding the alcohol to be tested. The reaction is sensible to $\frac{1}{1000}$ part of furfural in the alcohol, but where the quantity is slight the amount of alcohol tested must be increased, 2 c.c. being required for the detection of the proportion just named. Of course the absence of bodies, such as sugar, yielding furfural on contact with HCl must be ascertained, but aldehyde, acetone, and amyl alcohol are without effect on the reaction.—C. S.

Albuminoid and Phenols, Some Reactions of. E. Ackermann. Rev. Chim. Indust. 1895, 6, 322.

TREATED with Millon's reagent, albuminoids yield a deep red colour, which appears slowly in the cold and rapidly at

REACTIONS OF MILLON'S REAGENT WITH VARIOUS PHENOLS AND PHENOLOID SUBSTANCES.

the boiling point. The same colour is also characteristic of certain phenols; while, in the cold, the reaction may or may not be obtained, according to the manner in which the mercuric nitrate is prepared. The blood-red colour produced by a solution of titanous acid in sulphuric acid on phenols is also common to albuminoids in the dry state; and the red colour formed by the action of sulphuric acid in presence of sugar on the albuminoids, is yielded by certain phenols: resorcinol, naphthol, creosote, guaiacol, &c., and also by such bodies as morphine.

The colours recorded in the table were obtained by acting on 0.01 grm. of the substance with about 20 drops of the following reagents:—1. Millon's reagent—prepared by dissolving mercury in an equal weight of cold strong nitric acid, warming, adding double the volume of water, and decanting the clear portion after 24 hours. 2. Mercuric nitrate dissolved in a little water. 3. One part of mercuric oxide and two of nitrate in four of nitric acid. 4. One part of the nitrate in three of nitric acid.

Thymol and Carvacrol, Test for. W. G. Correll. Pharm. Review, 14, 33.

THESE substances are characterised by a beautiful purple-red coloration, produced by heating 0.01 grm. of such an oil as *Pycnanthemum lanceolatum* with 0.01 grm. of caustic potash and 20 drops of chloroform. Commercial carvacrol and thymol both give the same colour, as do also the oils of monarda and thyme, which are known to contain these phenols. Three samples of pennyroyal oil, two each of spearmint and turpentine oils, and one each of the oils of spike, lavender, rosemary, balm, peppermint, juniper, savin, cedar, balsam, fir, and white spruce were examined, but none of them gave this reaction, so characteristic for carvacrol and thymol.—W. S.

Sugar, The Action of, on Ammoniacal Silver Nitrate. J. Henderson. Proc. Chem. Soc. 1895, [159], 9.

THE author has investigated the reducing powers of the following substances on ammoniacal silver nitrate, viz., glucose, levulose, galactose, cane-sugar, starch, dextrin, lactose, and maltose. The results obtained may be thus summarised:—

(1.) When glucose, levulose, and galactose are heated with ammoniacal silver nitrate under the given conditions, a definite factor can be found in each case.

(2.) Cane-sugar, starch, and dextrin, when heated under the same conditions, exert no reducing action on ammoniacal silver nitrate.

(3.) In the case of lactose and maltose a definite factor cannot be obtained, owing to the gradual hydrolysis of the disaccharide by the ammonia.

ORGANIC CHEMISTRY.—QUANTITATIVE.

Asphalts, Analysis of. S. P. Sadler. J. Franklin Inst. 1895, 5, 383—386.

THE author proposes the following plan as an improvement on that elaborated by L. A. Linton (this Journal, 1895, 315): 1—2 grms. of the finely-powdered sample are mixed with 10 grms. of sand carried on a felt of asbestos in a weighed Gooch crucible. The whole is dried at 100° C. and weighed. If the sample be a "maltha" (liquid bitumen), it is gently mixed with the sand layer, after slightly softening it in the drying oven. The crucible and contents are placed in a continuous-extraction apparatus formed by a small percolator within a larger, the inner percolator being held in position by a perforated cork. The outer percolator is connected with a flask and a vertical condenser, and extraction with acetone carried on until the loss of weight of the crucible and contents in 2 hours, does not exceed 2 mgrms. The matter extracted as acetone is reckoned as "petroleum." The extraction is continued with chloroform, the fraction thus extracted being called "asphaltene." A total extraction of 12 hours with acetone and 8 hours with chloroform usually suffices. The crucible containing the insoluble organic matter and ash, is then ignited in the ordinary way. Refined Trinidad asphalt tested in this manner was found to have the composition:

petroleum, 46.40; asphaltene, 15.14; organic non-bituminous matter, 3.02; ash, 35.44.—B. B.

Linseed Oil and Varnish, The Examination of. H. Amsel. Rev. Chim. Indust. 1895, 6, 313, and 1896, 7, 13.

LINSEED oil ought to be kept at least one or two years after expression, being drawn off from one tank to another every three months. Spread as a thin film on glass, it should then dry in three days, the glass plates being kept in a sloping position, about 30° from the horizontal, during the test.

Of the new low-temperature methods of making varnish, that devised by Andés is considered by Amsel as the best, the oil being heated to 132° C. in presence of oxygen or unstable metallic oxides. Summer has brought out a new varnish substitute, consisting of a mixture of fish oil and a hydrocarbon such as benzene or light petroleum. To remove the free fatty acids, the varnish is subjected to a current of dry air until all acid vapours have disappeared, a little terebenthine being added, and also some manganese soap if the varnish is to dry quickly.

Linseed oil yields, as harya number, 18.7; rape oil, 17.6; and fish oils, 25.2 to 52.8.

The author holds that the saponification number is a good index of the purity both of oil and varnish, whilst if the alcoholic soap solution obtained in the process before titration is diluted with water, the mixture should remain perfectly clear. (See also this Journal, 1895, 605.)

—F. H. L.

Beet Juice, Acids, Mineral and Organic, in, Simultaneous Determination of. D. Sidersky. Comptes rend. 1895, 121, 1164—1165.

THE alcoholic fermentation of beet juice is largely influenced by the proportion of organic acids set free by the added sulphuric acid to the amount of the latter remaining unsaturated. The differential determination of these acids may be effected by the use of suitable indicators. Blotting paper moistened with a $\frac{1}{10}$ per cent. aqueous solution of Congo Red 4 R' is turned blue by free mineral acids, whilst it is unaffected by free organic acids.

A still more delicate method is to make use of the colouring matter present in the juice. In beet juice a substance is present which rapidly absorbs oxygen from the air with the production of a reddish-brown coloration. This oxidation is, however, hindered by the presence of free sulphuric acid, the latter producing a clear and pale liquid. If now a titrated solution of potash be added (the titration being carried out in a shallow basin) the reddish-brown colour is noticeable and very distinct as soon as the free sulphuric acid is neutralised. The two methods give very concordant results, but the latter one is the simpler. The mineral acid found subtracted from the total acidity, of course gives the organic acid. High total acidity with a low proportion of mineral acid is disadvantageous to fermentation.—L. T. T.

Levulose, Estimation of, in Honey and other Substances. H. W. Wiley. J. Amer. Chem. Soc. 1896, 18, 81—90.

THE method described, is based upon the change in specific rotatory power which levulose exhibits when submitted to changes in temperature. A convenient form of jacket for the observation tube is described, and renders the employment of different temperatures comparatively easy. The observation temperatures recommended are 0° and 88°, but intermediate temperatures may also be employed, the specific rotatory power of levulose at the temperatures named being $[\alpha]_D = 108.21^\circ$ and 53.0° respectively. The solution to be tested should contain approximately 14 grms. of levulose in 100 c.c., and this is usually the case when about 38.5 grms. of honey are used in the estimation. The formula for calculating the results is:—

$$L = \frac{R}{K(t - t')} \div W, \text{ in which}$$

K = deviation in divisions of cane-sugar scale, or in angular rotation produced by 1 grm. of levulose for 1° temperature.

T and T' = the temperatures at which observations are made.

R = observed deviation in rotation.
W = weight of levulose obtained.
L = per cent. of levulose required.—A. K. M.

Wine, Estimation of Alcohol and Extract by the Refractometer. E. Riegler. Zeits. Anal. Chem. 1896, **35**, 27—31.

By this method the alcohol and extract in wine may be rapidly determined, with consumption of comparatively little material. The data required are the refractive indices of—

1. The original wine = N.
2. The de-alcoholised wine, diluted to its original volume with water = b.
3. Distilled water = a.

The observations should all be made at the same temperature, and with an instrument yielding results accurate to 5 decimal places. Then—

$$\frac{N-b}{0.00068} = \text{alcohol in grms. per 100 c.c. of wine.}$$

$$\frac{b-a}{0.00145} = \text{extract, " " " "}$$

The above formulæ are, of course, purely empirical, but appear to yield satisfactory results, and are, according to one analysis, also applicable to beer.—H. T. P.

Butter, Testing of, by Viscosity Determinations. Pollenske. Apoth. Zeit. **11**, 97.

By direction of the German Sanitary Department the author tested the method of determining adulteration by estimations of viscosity, as suggested by Killing. He has found that the viscosity of butter varies so much that a very considerable admixture of margarin might escape detection.

—W. S.

Bergamot, Oil of, Examination as to Purity.

A. Bornträger. Zeits. Anal. Chem. 1896, **35**, 35—38.

The proportion of linalyl acetate ($C_{10}H_{17}O \cdot C_2H_3O$) existing in oil of bergamot, appears to be sufficiently constant to serve as a criterion of purity. According to Schimmel and Co. (this Journal, 1895, 605) the genuine oil contains 34—43 per cent. of linalyl acetate; although inferior samples from immature fruit or press residues, especially when prepared by steam distillation, may contain considerably less. Campelo found in five specimens obtained by pressure (not distilled) 37.6—39.9 per cent. of ester. The latter figures the author considers to be fairly representative, and therefore adopts 38 per cent. of acetate as a minimum standard. The determination of linalyl acetate is made by boiling 1—2 grms. of the oil with 10—20 c.c. of semi-normal alcoholic potash for 1—1½ hours, the unconsumed alkali being finally titrated in the usual way. The proportion of free acid contained in oil of bergamot is, as a rule, very small, and may be neglected; but is readily determined by direct titration in alcoholic solution.

Oil of turpentine, the adulterant most frequently employed, yields, when tested as above, 1.1—1.5 per cent. of (apparent) linalyl acetate; any gross addition (exceeding 10—25 per cent.) of the same to oil of bergamot would therefore be at once detected. The deficiency in saponifiable matters, due to adulteration with turpentine, may, however, be made good by the simultaneous addition of fixed oils (and possibly rosin, acid anhydrides, &c.), so that the above test would fail to indicate the adulteration. For this reason the non-volatile matters should be determined—at least, in the case of samples not yielding a clear mixture with 1½—2 volumes of 80 per cent. alcohol—by heating 2—5 grms. of the oil on a water-bath until odourless. The weight of the residue should not exceed 6 per cent. of the whole. In any case the presence of rosin would be indicated by a relatively high percentage of free acid (abietic acid, &c.).—H. T. P.

Alkaloids, Volumetric Determination of, by Means of Iodine Solutions. C. Kippenberger. Zeits. Anal. Chem. 1896, **35**, 19—27.

THE author describes a general method for the titration of alkaloids, and to this end has investigated the composition of the super-iodide precipitates produced by the interaction of alkaloid, iodine and potassium iodide—and, in some cases,

hydriodic acid—solutions in varying proportions. In every case the unconsumed iodine and potassium iodide remaining in solution were estimated by titration with thiosulphate, the combined iodine (KI) being for this purpose liberated by means of potassium bichromate and sulphuric acid, and extracted by chloroform prior to titration. The results (in respect to narcotine, strychnine, and atropine) are tabulated.

As a rule the proportions of iodine and potassium iodide consumed, are considerably in excess of those demanded by the equation $Alk. HCl + KI + I_2 = Alk. HI. I_3 + KCl$, and are subject to fluctuations depending chiefly on the concentration of the solution in potassium iodide and the excess of the latter employed. This is explained on the theory that at first alkaloid hydriodide and hydrogen peroxide are formed by the action of the free iodine. The peroxide then attacks the potassium iodide present, setting free iodine, which at the moment of liberation is mechanically carried down and retained by the super-iodide precipitate. In confirmation hereof, iodine could frequently be extracted from the precipitates by treatment with strong potassium iodide solution.

The author concludes, however, that reliable quantitative results may be obtained, providing the actual analysis and the standardisation of the iodine solution be effected under as nearly as possible identical conditions as regards quantity and species of alkaloid, concentration of its solution, excess of reagent employed, &c. By trial, the proportion of potassium iodide that must be used in order to arrive at a consumption of 31:1 Alk. is readily found. In the case of strychnine solutions, however, by first adding potassium iodide and then, immediately afterwards, iodine in excess, the consumption of the latter is reduced to the theoretical amount (2 atoms).—H. T. P.

Ergot, Valuation of. H. Beckurts. Oesterr. Zeits. **1**, 31.

A VARIETY of samples was examined—Russian, Austrian, Spanish, and German. It was found that by percolation with petroleum spirit, the fixed oil but no alkaloid was removed. 25 grms. of each sample were therefore freed from oil by that means, dried, and shaken with 100 grms. of ether and 1 gm. of magnesia, previously suspended in 20 c.c. of water. 60 grms. of the ethereal solution were freed from alkaloid by repeated agitation with 0.5 per cent. hydrochloric acid, from which the alkaloid was then removed by ammonia and ether. The ether-ammoniacal liquid on evaporation left a yellowish-white crystalline residue of alkaloid. The determinations agreed with those previously made by Keller. It was shown that Russian and Austrian ergots were the best, the richest containing 0.2 per cent., whilst the best German yielded 0.15 and Spanish 0.14 per cent. Drying by artificial heat diminished the yield of alkaloid by about 10 per cent.—W. S.

Mercurous Tannate, Determination of Mercury in. C. Glücks-mann. Oesterr. Zeits. **1**, 147.

THE method of mercury determination usually adopted in the case of this preparation, the author finds to be unreliable. He prefers to dissolve the substance in aqua regia, dilute with water, reduce by means of a solution of pure barium hypophosphite acidified with hydrochloric acid, the precipitated mercurous chloride being filtered off. This is then dissolved in a measured quantity of decinormal solution of iodine with the aid of a little KI, and the excess of iodine is removed by a measured quantity of decinormal solution of sodium thiosulphate, the excess of which is determined by titrating back with the iodine solution. The author claims that quick and accurate results are attainable by his method.—W. S.

Alkaline Benzoates, New Method of Determining, by Titration. G. Rebière. J. de Pharm. et de Chim. 1896, **3**, (3), 113—116.

A WEIGHTED quantity of the benzoate is dissolved in water, hydrochloric acid added in slight excess, and the whole is evaporated to dryness so as to volatilise, not only the excess of hydrochloric acid, but also the whole of the benzoic acid. The base remains as chloride, and in this chloride the chlorine is determined volumetrically by Mohr's method

with the aid of decinormal silver nitrate. The same weight of the benzoate is again dissolved in water and the amount of sulphuric acid necessary to exactly unite with the base is calculated from the previous process (Mohr's titration), and this is then added to the solution. The benzoic acid will thus be set free by its precise equivalent of sulphuric acid thus added, and can be determined by standard alkali, using phenolphthalein as indicator. The results are said to be exact. The method cannot be used for ammonium benzoate owing to the volatility of ammonium chloride, but the difficulty is overcome as follows:—A known weight of ammonium salt is dissolved in decinormal caustic soda, and the mixture is heated to boiling to expel ammonia, the complete expulsion of which is ascertained by the approach of a glass rod, the end of which is moistened with Nessler reagent. Thus a solution of sodium benzoate is obtained, plus the excess of soda employed. This excess is determined with decinormal sulphuric acid. Another equal weight of ammonium salt is then treated with the exact quantity of decinormal sulphuric or hydrochloric acid to unite with the ammonium, and the benzoic acid is determined as before.—W. S.

Nitrogen, Determination of, by the Absolute Method, A Difficulty in. Wyndham R. Dunstan and F. H. Carr. Proc. Chem. Soc. 1896, 48—49.

The percentage of nitrogen in acetonitrile determined by the soda-lime process, using the base, or by the absolute method, using the hydrochloride, agrees well with that calculated from the formula $C_3H_3N_2O$, which is 2.1 per cent. A few years ago Richards and Rogers (Chemist and Druggist, 38, 242) stated that when the amount of nitrogen in acetonitrile is determined in the usual manner by the absolute method, it is found to correspond with nearly twice the percentage calculated from the formula given above, and they therefore proposed to alter the formula of acetonitrile to $C_{30}H_{40}N_2O_{12}$, in accordance with the results of their determinations. Recently the authors have had occasion to determine the nitrogen in the base by the absolute method, the air being expelled from the combustion tube by carbon dioxide and the gas collected in an azetometer. They were surprised to find that over 4 per cent. of gas was obtained instead of 2.1 per cent., the calculated quantity.

A quantity of this gas having been collected in different experiments which had given too high results, a complete analysis of it was made. Nitric oxide and carbon monoxide were absent. By exploding with excess of oxygen, measuring the contraction, and absorbing the carbon dioxide, methane was proved to be present. Estimating the methane in the mixed gas, and deducting it from the total volume taken, the nitrogen amounted to almost exactly 2.1 per cent., corresponding with that calculated from the formula $C_3H_3N_2O$.

Experiments made with artificially prepared mixtures have shown that when largely diluted with nitrogen, methane is burnt very slowly and with difficulty by red-hot copper oxide. In conducting the process in the usual manner the influence of the carbon dioxide used to expel the air from the tube, no doubt greatly aggravates the difficulty. Acetonitrile seems to be exceptional in giving rise to so much methane during combustion. Possibly the difficulty might be overcome by mixing the alkalioid, not merely with finely powdered copper oxide, but also with a more powerful oxidising agent, as, for example, lead chromate. Neither acetonitrile hydrochloride, benzoconiac, nor acetonitrile hydrochloride present this anomaly, and it has been observed that if acetonitrile be introduced into the tube along with a little cuprous chloride, the percentage of nitrogen gas obtained corresponds very nearly with the calculated quantity.

XXIV.—SCIENTIFIC AND TECHNICAL NOTES.

Hydrogen Peroxide and Nitrous Acid; Reaction between in very Dilute Solutions. L. I. von Nagy Hlosva. Ber. 1895, 28, 2031—2032.

Highly dilute solutions (1:1,000,000) of hydrogen peroxide and nitrous acid were mixed and tested at intervals for hydrogen peroxide by means of aniline or *p*-toluidine (see page 216); for nitrous acid by means of sulphacetic acid and naphthylamine. It was found that:—

The mutual decomposition of hydrogen peroxide and nitrous acid, when existing side by side in equivalent amounts, proceeds very slowly, and is not complete even after 15—60 hours. When one of them, however, is present in excess, as compared with the other, the reaction proceeds more rapidly. The destruction of hydrogen peroxide is immediate and complete in presence of 15—20 times the amount of nitrous acid required by theory ($H_2O_2 + HNO_2 = H_2O + HNO_3$). On the other hand, nitrous acid proved far more resistant, and required for its immediate oxidation 800—1,200 times the theoretical amount of hydrogen peroxide. In any case their interaction is accelerated by direct sunlight, and proceeds somewhat more rapidly in acid than in alkaline solution.—H. T. P.

The Ferrates. C. A. O. Rosell. J. Amer. Chem. Soc. 1895, 17, 700.

The author succeeded in preparing sodium ferrate in the dry way by fusing ferric oxide with sodium peroxide. The fused mixture was treated with ice, and sodium ferrate thus obtained in aqueous solution. When water was added to the fused mass instead of ice, the resulting heat was sufficient to decompose the sodium ferrate.

Attempts to prepare iron dioxide failed, clearly proving that if this compound exist at all, it is so unstable that it is decomposed as soon as formed.

Carbon dioxide was passed through water containing barium ferrate in suspension; the barium ferrate was decomposed with formation of barium carbonate and ferric hydroxide, oxygen being set free. Barium ferrate was decomposed by hydrochloric acid with formation of chlorine. Barium chromate was digested with a solution of sodium ferrate, barium ferrate being formed along with sodium chromate. The author could not get the reverse action to take place. An alkaline sulphate decomposed barium ferrate which had not been dried, with formation of barium sulphate and ferric hydroxide, oxygen being set free.

The author found that the soluble ferrates were decomposed by nearly all soluble organic compounds, the most notable exceptions being the formates and acetates. They were also decomposed by some insoluble organic compounds, such as paper and the insoluble carbohydrates, but only very slowly by benzene and the paraffins.

The author found that the best way to prepare the alkaline ferrates was to pass chlorine through a strong

solution of the hydroxide containing ferric hydroxide in suspension.

The author points out the following errors in the literature of the ferrates:—1. The preparation of potassium ferrate by adding iron nitrites to caustic potash (Stahl). 2. That a solution of potassium ferrate turns green on standing (J. Denham Smith). 3. The insolubility of calcium ferrate in water (Fremy). 4. The preparation of thioferrates by passing hydrogen sulphide through a solution of a ferrate (Fremy). 5. The allegation that sodium ferrate cannot be made except in the wet way (Wurtz).

Fixation of Nitrogen by the Metals of the Alkaline Earths. L. Maquenne. Comptes rend. 1895, 121, 1147—1148.

THE author calls attention to the fact, previously described by him, that the metals of the alkaline earths readily absorb nitrogen at a dark red heat. If a mixture of magnesium powder and lime be raised to a dull red heat, metallic calcium is freely liberated in a finely divided state. This mixture, at the same temperature, rapidly absorbs nitrogen with the formation of calcium nitride, Ca_3N_2 , and this latter compound is decomposed by water with evolution of ammonia. The lime may be replaced by barium oxide, but the absorptive power of the reduced barium for nitrogen is weaker than that of the calcium.—L. T. T.

Transparency of Ivory. Method of Modifying the. C. Raspe, Weissensee, Berlin, Germany. Eng. Pat. 24,928, Dec. 30, 1895.

THE glassy ivory is heated in oil, paraffin, turpentine, or glycerin for from 5 to 20 minutes at a temperature above 212°F , the actual temperature employed depending on the degree of turbidity required in the ivory. After removal of the adhering oil, &c. has been effected by a suitable solvent, the ivory is bleached by known methods.—A. G. B.

New Books.

HANDWÖRTERBUCH DER PHARMACIE. Praktisches Handbuch für Apotheker, Ärzte, Medicinalbeamte und Drogisten. Herausgegeben von A. BRESTOWSKI, Wilhelm Braumüller, k. u. k. Hof- und Universitäts-Buchhändler, Wien und Leipzig. 1895. H. Grevel and Co., 33, King Street, Covent Garden, London. Price per number, M. 2.40.

This number completes the entire work, and forms Part 24. It commences on page 865 with a continuation of the article on Sugar, which is completed on the following page (866). Two pages further on, the ordinary text of the work is concluded. An Appendix then follows, and extends from page 869 to 884, beginning with "*Acetamido-antipyrin*" and ending with "*Urotropin*" (*Formin*). The Alphabetical Index then follows. It fills 57 pages, and Lists of Errata for Volumes I. and II. conclude the work.

CHEMISCHE PRÄPARATENKUNDE. Von Dr. ADOLF BENDER und Dr. HUGO ERDMANN. Band II. Anleitung zur Darstellung organischer Präparate von Dr. HUGO ERDMANN. Mit 41 in den Text gedruckten Abbildungen.

Verlag von Ferdinand Enke, Stuttgart. 1894. H. Grevel and Co., 33, King Street, Covent Garden, London. Price M. 14 or 14s.

THE first volume of this work, devoted to the Preparation of Inorganic Substances, by Dr. A. Bender, has been already noticed in this Journal, 1893, 719. The present is the second and concluding volume, devoted to the Preparation of Organic Substances. It is an 8vo volume, in paper cover, and contains Preface, Table of Contents, Subject-Matter covering 590 pages, a List of the best sources of information in the shape of Journals and Text-Books, an Index (alphabetical) of all necessary raw materials needed for the preparations referred to, with sources of supply, and the Alphabetical Index of the volume. The text is illustrated with 41 well executed engravings representing the apparatus recommended, and is sub divided as follows:—

A. The Arrangement of a Laboratory for Organic Preparations. B. Hydrocarbons and their Halogen Derivatives. C. Groups of Alcohols and Phenols. D. Groups of Aldehydes and Ketones. E. Groups of Carboxylic Acids and Esters. F. Metallic Compounds of the Alcohols, Esters, and Hydroxy Acids. G. Iodo- and Iodoso-Compounds. H. Nitro-Compounds and Nitro-Esters. I. Nitroso-Compounds and Oximes. K. Group of Bases. L. Diazo-Compounds. M. Azo-Compounds. N. Cyanogen Compounds and Nitriles. O. Thio-Compounds. P. Sulphonic Acids. Q. Mercury Compounds.

CHEMISTRY FOR ENGINEERS AND MANUFACTURERS: A Practical Text-Book. By BERTRAM BLOUNT, F.C.S., F.I.C., and A. G. BLOXAM, F.C.S., F.I.C. Vol. I.—Chemistry of Engineering, Building, and Metallurgy. Charles Griffin and Co., Ltd., Exeter Street, Strand, London. 1896. Price 10s. 6d.

THIS is the first of two volumes, which will form the entire work. It is of large 8vo size, and is illustrated with 35 wood engravings. The authors in their Preface state that the chief object in view has been "the needs of practising Engineers, Managers of Works, and Technical Students desirous of obtaining some knowledge of Chemical Technology."

The text of Vol. I. covers 244 pages, including the Alphabetical Index.

The work is planned out according to the following divisions and sub-divisions:—

PART I.—I. Chemistry of the Chief Materials of Construction. II. The Chemistry of the Sources of Energy. III. The Chemistry of Steam Raising. IV. The Chemistry of Lubricants and Lubrication. PART II.—METALLURGY. Metalliferous Ores. Iron. Copper. Lead. Zinc. Cadmium. Tin. Antimony. Bismuth. Nickel. Cobalt. Mercury. Silver. Gold. Platinum Group of Metals. Metals difficult of Reduction.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

(From the Board of Trade Journal.)

FRANCE.

Regulations affecting the Port of St. Nazaire.

The *Journal Officiel* of February 9th last, contains a Presidential decree, by which the Custom-house of St. Nazaire is added to others previously designated for the importation, under the rules for temporary admission, of chlorate of potash for conversion into chlorate of soda or of baryta.

SPAIN.

Oleo-Naphtha and Lubricating Oils.

According to the *Journal Officiel*, by a Royal order of December 10th, 1895, oleo-naphtha, lubricating oils, and other articles comprised in paragraphs 8 and 9 of the

tariff, imported in barrels or otherwise, will pay duty according to their net weight, tare being allowed for the recipients.

AUSTRIA-HUNGARY.

The *Bollettino di Notizie Commerciali* publishes extracts from ordinances of the Austro-Hungarian Customs, by which an additional 13 per cent. is to be added to the net weight of liquid chlorate (? chloride) of zinc imported in tank waggons.

UNITED STATES.

Crude potassium metal is to pay duty at the rate of 20 per cent. under section 3.

Magnesium powder is free of duty under paragraph 544.

JAPAN.

Duties to be charged on British Imports. Tariff.

No.	Articles.	Duty.
		Yen.
1	Caoutchouc, manufactures of	10 <i>ad val.</i>
2	Cement, Portland,	100 catties 0.065
18	Glass, window, ordinary:— (a.) Uncoloured and unstained	100 sq. ft. 0.302
	(b.) Coloured, stained, and ground,	10 <i>ad val.</i>
20	Indigo, dry	100 catties 12.953
32	Lead, pig, ingot, and slab	" 0.316
33	Leather:— (a.) Sole	10 " 5.690
	(b.) Other kinds,	10 " <i>ad val.</i>
37	Mercury or quicksilver	100 catties 5.948
39	Oil, paraffin	10 " <i>ad val.</i>
40	Paint in oil	100 catties 1.304
41	Paper, printing	" 1.163
42	Saltpetre (nitrate of potash)	" 0.490
47	Sugar, refined:— (a.) No. 15 to No. 20, inclusive, Dutch standard in colour,	" 0.748
	(b.) Above No. 20 Dutch standard in colour,	" 0.827
	Tin:—	
48	Block, pig, and slab,	10 " 1.902
49	Plates	10 " <i>ad val.</i>
	Zinc:—	
63	Block, pig, and slab,	100 catties 0.451
64	Sheet	" 0.928

Weights, Measures, and Coins.

The catty mentioned in this tariff is the Japanese weight. It is equal to 600 grms. of the metric system of weights, or 1.32277 lb. English avoirdupois weight.

The pound is the English avoirdupois weight.

The square yard and square foot are the English Imperial surface measures.

The yen is the present Japanese silver yen of 900 fineness and 416 grains in weight.

Rule for Calculating ad valorem Duties.

Import duties payable *ad valorem* under this tariff shall be calculated on the actual cost of the articles at the place of purchase, production, or fabrication, with the addition of the cost of insurance and transportation from the place of purchase, production, and fabrication, to the port of discharge, as well as commission, if any exists.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

PEAT-COAL IN NORWAY.

Board of Trade Journal, March 1896, 317.

A report has been received from Her Majesty's Acting Consul-General at Christiania, enclosing specimen of a new fuel, peat-coal, together with report of the inventor, Mr. William Schöning, who claims to have discovered a practical means of converting peat into a cheap and valuable fuel.

Mr. W. Schöning states that he presses the peat, at the same time carbonising (charring) it in the press.

The new fuel was analysed by Mr. Schmeleck, analyst to the City of Christiania, with the following results:—

	Per Cent.
Carbon	66.15
Hydrogen	6.60
Oxygen	17.75
Nitrogen	1.86
Sulphur	0.38
Ash	3.76
Moisture	3.50
	100.00

According to Mr. Schmeleck's further analysis it has a calorific value of 6,556 calories per kilo.

THE CAMPHOR TRADE.

Board of Trade Journal, March 1896, 281.

The following particulars concerning the camphor trade are based on the "Official Returns of Trade" for 1894, compiled by the Chinese Imperial Maritime Customs, on reports by (1) Sir Ernest Satow, Her Majesty's Minister at Tokio in 1895; (2) Her Majesty's Consul at Hiogo in 1892 and 1895; (3) M. Klobukowski, Consul-General for the French Republic at Yokohama; and (4) on a special report on the island of Formosa, furnished by Mr. N. Perkins, Assistant in Her Majesty's Consular service.

In times gone by camphor was produced in Sumatra and Borneo and in other parts of the East Indies, as well as in China; now, however, the crude camphor of commerce is a product of Japan proper and the island of Formosa exclusively.

Great difficulties remain to be surmounted before the Formosa trade can be depended on, for the trees are only found inland, where the inhabitants are aboriginal barbarians, who make matters most unpleasant for explorers.

The Formosa drug is inferior to the Japanese; the latter, by reason of its greater purity, pinkish colour, and bold grain commanding in foreign countries higher prices, by some 2 per cent. or 3 per cent., in spite of its comparative abundance.

The districts in Japan famed for camphor trees are Kinsu, Shikoku, Iga, Suruga, Isé, and Kishiu. The forests owned by the people are almost denuded of timber, and soon very little will be left. However, the Government forests are still very rich in camphor trees, and it has been estimated that this alone will maintain annually, during the next 25 years, the full average supply of crude camphor.

Formerly very little care was bestowed upon the preservation and cultivation of this valuable timber. More recently, however, not only the Government but also the people have been giving to this most important question the attention it long ago deserved.

The roots contain a much larger proportion of camphor than the trees, 10 lb. of crude camphor out of 200 lb. of wood-chips being thought satisfactory. The Suruga timber yields a much smaller percentage.

It appears that the only process of extracting camphor from the wood among the mountains in Japan, and the materials used, are of the roughest and most unscientific description. The wood-chips are boiled, the vapour being conducted into a receptacle containing several partitions surrounded by cold water. In the sides of these partitions are apertures, which cause the vapour to fill the divisions by a circuitous route, thus improving the grain of the camphor.

The crude article is brought to market, as a rule, in very rudely constructed wooden tubs.

To make it fit for shipment requires much work, diligence, and experience. Each tub is carefully sampled, vertically and diagonally, and the samples are tested by fire and sometimes by alcohol. If no solid adulterant is discovered, the condition of the drug is next inquired into, the difficulty of this step being best explained by at once stating that this crude camphor contains a quantity of water, or oil and water, varying anywhere between 5 per cent. and 20 per cent.

This trouble overcome, the rest is comparatively easy, and consists in weighing, cutting, mixing, and packing for

shipment, the packing being in tubs prepared on the premises, partly out of the original packages.

Of course the camphor cannot be packed in its crude condition; much of it has to be drained and dried, and frequently a special parcel of "dry" must be bought, at a very high figure, for mixing with it.

Exports of camphor from Japan appear to have increased in value, in proportion to the quantity, during the last 10 years, as the following table will show. In this case the value of the yen has been converted, at the average rate for the years given, which varies in each case.

Export of Camphor from Japan.

Years.	Quantity.	Value.
	Lb.	£
1886	7,267,000	151,000
1887	8,687,000	179,000
1888	6,074,000	153,000
1889	6,823,000	213,000
1890	5,952,000	314,000
1891	5,905,000	272,000
1892	1,419,000	186,000
1893	3,317,000	167,000
1894	2,762,000	109,000

An intelligent and well-directed exploitation of the island of Formosa, where the camphor tree is so abundant, would probably have the effect of lowering prices, by increasing the amount of camphor placed on the market.

The principal countries dealing in camphor are Hong Kong and the United States. The exports from Japan in 1894 were as follows:—

Countries.	Quantity.	Value.
	Lb.	£
Australia	10,600	918
India	78,800	6,096
China	6,600	268
France	4,100	302
Germany	13,100	7,459
United Kingdom	108,600	5,928
Hong Kong	1,654,300	87,524
United States	772,500	37,464
Other countries	2,900	162

Hong Kong is only a transit port where the camphor is refined previous to exportation to Europe.

A special feature of the year 1894 was a material reduction in business in camphor from Japan (as distinguished from camphor from Formosa, now also a part of Japan) in comparison with former years, attributable perhaps to the ever-increasing production of Formosa and the gradual improvement of the quality of the island product.

During the year there was a fraudulent attempt at mixing inferior Formosa camphor with Japanese produce, and passing it off as Japan camphor. Through the energetic and effective measures which were at once taken by leading camphor exporters, supported by the Japanese Chamber of Commerce, the attempt was discovered at once, and no such mixtures left the ports.

Another feature of remark was the formation of a guild amongst the native sellers, with the declared object of establishing a much-needed reform in quality by introducing certain new and uniform delivery terms, and these have no doubt done away with a great deal of the trouble and disputes previously existing.

Mr. N. Perkins, Assistant in Her Majesty's Consular Service, in his report on the island of Formosa, dated January 31, 1895, states that in the north of the island the trade in camphor is rapidly growing in importance; it is, however, attended by considerable risks, as heavy advances have to be made, and sometimes, whether due to the raids of savages or other causes, without any return, either in cash or camphor.

New districts are from time to time opened up, the chief at present being Hoonim or Yünlin, Kagee or Chia-I, Chip Chip, Polihsia, and Ao-doi-pö.

According to the returns of trade for the year 1894, compiled by the Chinese Imperial Maritime Customs, the exports of camphor from Tamsui in 1894 (almost entirely to Hong Kong) represented 91 per cent. of the total value of the trade, the total shipments having been 3,708,000 lb., of the value of 569,365 H. taels (about 91,000£.).

From the port of Tainan during 1894 the amount of camphor exported was 1,565,000 lb., of a value of 263,878 H. taels (about 42,200£.).

Tainan and Tamsui are the only two ports of Formosa where there is a camphor trade of any importance.

There are no available figures as to the amount of camphor exported from Formosa for any period subsequent to 1894, but according to a recent report of Sir Ernest Satow, Her Majesty's Minister at Tokio, the amount exported from Japan during the first six months of 1895 was 1,530,000 lb., of a value of 649,457 yen (about 69,000£.).

FRUIT-DRYING EXPERIMENT.

Cons. Reps., Ann. Series, 1895, No. 1652.

Mr. Wilfrid Powell, British Consul at Stettin, reports that a manager of a Government peat-moor, wishing to keep some apples and pears during the winter months, thought he would try packing them in "mull," that is to say, the dust obtained from the dry moss litter when being torn up by the disintegrator. In this mull, or dust, he packed a number of pears and apples, enclosing the whole in a wooden case, and pressing the mull well down, taking care that each fruit was kept a little distance from the other. At the end of three months he found the pears and apples perfectly dried and as sound as those prepared for commerce by the more elaborate methods, while on being placed in warm water they began to swell out again to their former proportions. Mull sells in Germany at about 1s. 3d. per cwt., and, as it is exceedingly light, 1 cwt. will dry a large quantity of fruit, while it can be used again many times over, has no smell, and does not convey any taste to the fruit. It merely absorbs the moisture which the fruit contains, at the same time protecting it from the air.

GENERAL TRADE NOTES.

MINERALS IN SOUTHERN RUSSIA.

Board of Trade Journal, March 1896, 329.

The *Revue Commerciale* of Berliansk, states that vast deposits of iron, graphite, kaolin, and other minerals have been found at the village of Grand Tounak and in German colonies; anthracite has been discovered near Orekhov at the village of Belitskoié. Specimens of kaolin have been already analysed at St. Petersburg, Berlin, and Marseilles; and it has been found that the quality is excellent for the manufacture of porcelain. As for the iron ore, it was said to contain from 62 to 72 per cent. of pure iron and very little sulphur or phosphorus, in which it resembles the celebrated ore of Krivoi-Rog.

PACKING BUTTER FOR EXPORT.

The *Australasian*, in a recent issue, states that one of the chief obstacles in the way of the successful development of the dairying industry has hitherto been found in the difficulty of discovering a cheap, clean, and attractive way of packing butter, honey, and other perishable farm products. It will come as a surprise to many to learn that a simple process has been discovered, and is now in operation in Australia, by which the inventors claim that they can supersede costly refrigerating plant completely, and despatch butter, honey, jam, and similar comestibles to any part of the world, with the certainty that when opened the article will be found in perfect condition.

How far these expectations are warranted by results already attained cannot as yet be stated definitely, but it is a fact that butter packed in Melbourne by the new process

has been opened at Kimberley, South Africa, 700 miles from Cape Town, and found to be as good as when it left the butter factory in Victoria.

By the new process, the butter is packed in a box made of six small sheets of ordinary glass, the points of juncture being covered with gummed paper. The glass casket is then covered with a mould of plaster of Paris about a quarter of an inch thick, which in turn is covered with specially prepared paper. The package then presents the appearance of a solid brick of plaster or cement, and as the plaster is a non-conductor of heat it is claimed that the butter packed hermetically inside is unaffected by any change of temperature. The prime cost of packing 1 lb. of butter in this way is about 1d., and the convenience and portability are obvious. The inventor states that these solid bricks of butter can be and have already been loaded on shipboard as ordinary cargo, and delivered in perfect condition in Coolgardie, Northern Queensland, and South Africa.

Cases manufactured in the same way, and capable of holding 2 cwt. of butter, have also been manufactured by the syndicate at its large factory, where 40 hands, principally boys and girls, are engaged in making the glass boxes and covering them with plaster of Paris, all except the top, which is put on afterwards by a simple mechanical device, and removed by the purchaser in an equally easy manner.

It is claimed that a saving of 25 per cent. is effected on freight and packing as compared with butter frozen and carried in the usual way. In the future the new invention may revolutionise present methods of dealing with dairy produce for export.

CYLINDERS FOR COMPRESSED GASES.—REPORT OF THE COMMITTEE.

Eyre and Spottiswoode, 1896.

After the explosion at Fenchurch Street Station, Mr. Asquith appointed a Departmental Committee of inquiry into the causes of such explosions, and the precautions necessary to ensure safety in dealing with cylinders of compressed gas. The Committee, which consisted of Profs. Unwin, Boys, and Dixon, with Dr. Dupré and the Rev. T. J. Smith (Lecturer on Mechanics, Oxford), has just issued its report and recommendations. A general official inspection of all factories manufacturing compressed or liquefied gases is recommended as being desirable, and it is suggested that such inspection might be conducted under the Factory Department of the Home Office, or even by a department of the Board of Trade.

For cylinders intended to contain oxygen, hydrogen, or coal-gas, the greatest working pressure recommended by the Committee is 120 atmospheres, or 1,800 lb. per square inch, the cylinders to be permanently marked with a rotation number, a manufacturer's or owner's mark, an annealing mark with date, and a test mark with date. Testing is recommended to be repeated every two years, and annealing at least every four years, a record being kept of all tests. Hydrogen and coal-gas cylinders should have left-handed threads, and be painted red, whilst a minimum weight should be fixed for each size of cylinder in accordance with its required thickness. The greatest working pressure recommended for cylinders for carbonic acid is also 120 atmospheres, and it is stated that no cylinder ought to contain more than $\frac{1}{4}$ lb. of carbonic acid per pound of water capacity, if for this country, or $\frac{2}{3}$ lb. if for the tropics. A notice ought to be affixed to the cylinder stating that it contains carbonic acid and should be kept cool, and not exposed to the sun. Ammonia cylinders are recommended to have a working pressure not exceeding 1,000 lb. per square inch, and they should not contain more than $\frac{1}{4}$ lb. of ammonia per pound of water capacity, whilst a similar notice should be affixed to that recommended for carbonic acid cylinders. No oil or similar lubricant should be used for cylinder valves, pressure gauges, regulators, or other fittings; pressure gauges should have a check to prevent a sudden inrush of gas, and those for hydrogen and coal-gas should have left-handed screws and be painted red. Several other recommendations are made with regard to minor details, and it is stated that, subject to a reasonable guarantee that all the

specified conditions are complied with, the Committee will be prepared to recommend that cylinders should be distributed by road or rail unpacked.

NEW SOUTH WALES PLATINUM.

Engineering and Mining Journal, February 22nd, 1896, 182.

In view of the enormously increased consumption of platinum in electrical work it is agreeable to note the well accredited statement that large deposits of this valuable mineral have been discovered at Fittfield, New South Wales. It has been known for several years that platinumiferous lead existed in this locality, and the deposits have been worked, though only on a small scale. It is now found, however, that the platinumiferous lead is over a mile long, varying in width from 60 ft. to 150 ft., and covered with from 60 ft. to 70 ft. of loam. The precious metals are practically confined to the bedrock and the drift for 3 ins. above the bottom. Nuggets which weighed from a few grains up to 5 dwts. have been occasionally found. The crude metal contains about 75 per cent. of platinum, and realises at the present time upon the field 24s. per oz.

THE CARRIAGE OF ACETYLENE AND CALCIUM CARBIDE IN GERMANY.

Chemist and Druggist, February 29th, 1896, 309.

The following regulations have been issued for the carriage of acetylene and calcium carbide on the German railways:—"The rules relating to the despatch of liquid carbonic acid and nitrous oxide are also to be applied to liquid acetylene, with the additional proviso that vessels used for acetylene-carriage may not contain any parts of copper, brass, or other copper alloys. The pressure-test is to be applied to all containers, and the maximum admissible is, for acetylene, 250 atmospheres and 1 kilo. of liquid for every 3 litres of space in the vessel. Calcium carbide must be packed in iron vessels closed air-tight, and no other goods may be added to any package containing either acetylene or calcium carbide."

MATCHES IN FRANCE.

Chemist and Druggist, March 14th, 1896, 372.

The match difficulty, which has given the French Government so much trouble for some time past, seems at last to be in a fair way to be solved. The problem has been to produce a match that offers no danger to the workers. A Dijon chemist, M. Pouteaux, now claims to have perfected a process by which permanganate of potash can be used for matches, the difficulty met with hitherto having been that all the glues used with this substance up to the present time decomposed the permanganate and thus rendered it useless. M. Pouteaux has succeeded in using a "glue" made by dissolving guncotton in acetate of amyl. The match is plunged into this mixture after having been steeped in sulphur in the first place. M. Pouteaux's matches will require a special striker, which is considered to be an objection to their becoming rapidly popular with the lower classes.

LAMP ACCIDENTS AND LAMP-OILS.

E. Stanford, 1896.

The official report of Mr. Alfred Spencer, chief officer of the Public Control Department of the London County Council, is a very full one, and replete with results of tests and experiments. He thinks that if no oil were burned below 100° F. close test, lamp accidents would be far less frequent, but he thinks the point would have to be raised to far above 100 to give a full measure of safety. He thinks it would be impracticable to fix that standard, and is of opinion that, if the lamps are properly made, accidents would cease gradually as the safe lamps replaced the unsafe ones. Mr. Spencer then discusses the construction of lamps at considerable length and in an interesting manner. He summarises his conclusions thus:—

1. That the number of accidents arising from the burning of mineral oil in lamps has increased and is still increasing, notwithstanding the voluntary efforts made for preventing them, and that effectual means of prevention can only be found in compulsory measures.

2. That raising the flash-point fixed by the Petroleum Acts would not alone be effectual in preventing lamp accidents, as this would not prevent the sale and use for illuminating purposes of oil below that flash-point.

3. That the prohibition of the retail sale and the prevention of the use for illuminating purposes of mineral oil below a flashing-point sufficiently high to prevent all lamp accidents would be effectual if it were practicable.

4. That the prohibition by statute of the sale of unsafe lamps would be another means of putting an end to lamp accidents, as both experience and experiment have proved that mineral oils such as are now in common use can be safely burnt in properly constructed lamps.

5. That a practicable method of preventing the sale of unsafe lamps would be by a clause similar to that submitted by me to the Select Committee on Petroleum in 1894, which is as follows:—

The Secretary of State may from time to time by order make, and when made, rescind and alter, specifications of lamps or other appliances intended to be used for burning mineral oil for the purposes of illumination, heating, cooking, or otherwise, and it shall be unlawful for any person on and after the day of

189 , to keep, expose, or offer for sale, or sell any such lamp or other appliance, unless constructed in accordance with one of such specifications, and any person keeping, exposing, or offering for sale, or selling any such lamp or other appliance not so constructed shall be liable, on conviction, to a penalty of not exceeding 5*l.* in respect of such lamp or other appliance, and to the forfeiture of the lamp or appliance.

As an appendix Mr. Spencer gives the recommendations as to lamps having metal reservoirs, wick-tubes, &c., which are already well known. (See also pages 173 to 179.)

GERMAN IMPORTS AND EXPORTS OF DYES AND COLOURS FOR THE TEN YEARS ENDING DECEMBER 1894.

Sawn	34,576	64,073	81,567	150,711
Staves	4,186	4,123	22,522	40,634
Mahogany	2,184	8,835	17,149	33,141
Other articles .. Value £	600,633	793,156
Total value	1,875,918	2,746,128

Besides the above, drugs to the value of £8,797, were imported, as against 55,626, in February 1895.

IMPORTS OF OILS FOR MONTH ENDING 29TH FEBRUARY.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Cocoa-nut	7,997	27,439	£ 8,767	£ 31,756
Olive	546	3,161	21,371	107,704
Palm	89,274	91,689	93,471	99,009
Petroleum	8,442,378	18,094,640	129,113	373,361
Seed	2,849	2,618	61,239	52,962
Train, &c.	917	927	16,625	15,496
Turpentine	11,176	10,698	10,745	10,810
Other articles .. Value £	62,103	83,327
Total value of oils	404,087	777,085

EXPORTS OF METALS (OTHER THAN MACHINERY) FOR
MONTH ENDING 29TH FEBRUARY.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Brass	7,856	11,630	£ 29,965	£ 41,660
Copper:—				
Unwrought	32,402	59,968	69,836	117,563
Wrought	18,149	38,116	48,353	100,645
Mixed metal	14,190	31,033	31,065	66,542
Hardware	124,487	156,149
Implements	77,688	104,672
Iron and steel .. Tons	157,830	237,346	1,294,758	1,728,089
Lead	2,338	2,808	29,679	37,390
Plated wares .. Value £	19,070	18,367
Telegraph wires	9,411	109,840
Tin	6,624	11,325	21,300	36,152
Zinc	14,351	18,840	9,367	11,738
Other articles .. Value £	16,964	60,885
Total value	1,811,973	2,589,075

EXPORTS OF DRUGS AND CHEMICALS FOR MONTH
ENDING 29TH FEBRUARY.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Alkali	394,760	340,031	£ 90,640	£ 90,666
Bleaching materials ..	98,446	92,755	31,319	33,123
Chemical manures .. Tons	25,034	36,516	194,423	194,467
Medicines	75,739	85,144
Other articles .. Value £	209,355	313,927
Total value	613,476	717,387

EXPORTS OF MISCELLANEOUS ARTICLES FOR MONTH
ENDING 29TH FEBRUARY.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Gunpowder	327,000	553,300	£ 7,326	£ 12,210
Military stores .. Value £	98,222	188,860
Candles	1,767,200	2,207,500	29,350	35,336
Caoutchouc	80,446	92,181
Cement	14,347	27,512	23,160	45,591
Products of coal .. Value £	105,075	174,211
Earthenware	120,512	139,534
Stone-ware	8,304	10,669
Glass:—				
Plate	92,048	150,120	4,781	8,205
Flint	6,336	7,479	13,991	16,514
Bottles	45,770	56,299	21,861	26,534
Other kinds	13,316	17,844	10,317	13,404
Leather:—				
Unwrought	9,429	9,807	88,711	99,662
Wrought	24,296	29,524
Seed oil	3,171	4,442	63,548	85,074
Floer cloth	2,273,600	2,359,800	73,279	92,616
Painters' materials .. Value £	101,568	135,337
Paper	60,677	74,556	97,916	116,771
Rags	2,790	4,479	17,779	23,836
Soap	38,094	55,967	40,956	56,185
Total value	2,005,897	2,660,224

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

3543. H. Smithurst. Improvements in or relating to pressure and vacuum gauges. Feb. 17.

3569. E. Petzholtz. Improvements in or connected with furnaces. Complete Specification. Feb. 17.

3572. S. S. Bromhead.—From Dierks and Mollmann. Improvements in sterilising apparatus. Feb. 17.

3575. A. J. Boulton.—From M. W. Judell. New or improved heating or cooling agent. Complete Specification. Feb. 17.

3668. T. Jenkins. Improvements in hydro-extractors. Complete Specification. Feb. 18.

3859. A. Ludwig.—From S. Moser. Improvements in the apparatus for evaporating vegetable and animal matter, commonly known as Ryder's evaporator. Complete Specification. Feb. 20.

4208. W. Griffiths and V. C. Read. Improvements in and in apparatus for treating feed water to prevent incrustation in boilers, applicable for treating or purifying water for other purposes. Complete Specification. Feb. 25.

4241. C. G. J. Moller and P. Pfeifer. Improvements in drying apparatus. Feb. 25.

4253. E. C. Nichols. Improvements in apparatus for compressing and storing air. Complete Specification. Feb. 25.

4266. H. J. Fraser. Improvements in evaporative and other condensers, evaporators, and the like. Feb. 25.

4328. H. H. Lake.—From D. N. Maxon. Improvements in apparatus for use in fusing refractory substances. Feb. 26.

4418. H. H. Lake.—From W. F. Jobbins and J. van Ruymbeke. Improvements in evaporating apparatus. Complete Specification. Feb. 27.

4604. E. Theisen. Improvements in apparatus for evaporating, condensing, and cooling fluids. Complete Specification. Feb. 29.

4725. W. L. Wise.—From Solvay et Cie. Improvements in apparatus for filtering, washing, and drying, suitable for the treatment of bicarbonate of soda. March 2.

5409. S. Pitt.—From La Compagnie Internationale des Procédés A. Seigle. An automatic re-ignition apparatus for hydrocarbon furnaces. March 10.

5431. S. M. Lillie. Improvements in evaporating apparatus. March 10.

5556. H. S. Young and C. J. Ellis. Improvements in filtering apparatus. March 12.

5766. La Société Anonyme dite "Blanchisserie et Teinturerie de Thaon." Improvements in apparatus for use in drying fabrics. March 14.

COMPLETE SPECIFICATIONS ACCEPTED.*

1895.

1415. C. Pratten. Improvements in presses suitable for moulding plastic materials and subsequently dividing the same into blocks. March 4.

5103. E. C. Mills and J. G. Chamberlain. Surface condensers. March 4.

5113. P. F. Holmes. Apparatus for washing gases. March 11.

6211. M. Arndt. Apparatus for weighing gases. March 18.

10,905. B. L. de Ridder. Apparatus for sampling gases for analysis. March 18.

16,052. F. D. Cammer. Apparatus for drying by means of furnace gases and air. March 18.

18,464. J. Wood. Improvements in and connected with furnace pans, coppers, and the like. Feb. 26.

22,582. E. B. Caird and T. J. Rayner. Air-cooled condensers. March 18.

1896.

947. C. E. Mumford. Improvements in apparatus for turning malt and like materials on a kiln floor. March 11.

2925. E. B. Caird and T. J. Rayner. Surface condensers and coolers. March 18.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

3560. A. Quentin. Improvements in apparatus for burning liquid fuel. Feb. 17.

3681. W. Mackean and the Incandescent Gas Light Company, Limited. Improvements in the manufacture of mantles for incandescent gas lighting. Feb. 18.

3937. W. Rockliffe. Improved means for producing artificial light. Feb. 21.

3982. E. J. Shaw. Improvements in incandescent gas lamps or burners. Feb. 21.

4000. W. Nicholls. Improvements in the manufacture of incandescence bodies for illuminating purposes. Feb. 21.

4192. A. Morgan. Improvements in gas heating and lighting. Complete Specification. Feb. 25.

4285. J. R. Wigham. A method of burning acetylene gas or other very rich hydrocarbon gas. Feb. 26.

4345. J. H. Dunn and R. G. E. Dalrymple. See Class XI.

4402. W. B. Kirkwood. A new or improved lamp for generating and consuming acetylene gas. Feb. 27.

4419. J. C. Hunauer. An improved apparatus for making and carburetting hydrogen gas. Feb. 27.

4421. J. Anderson.—From W. Anderson. A shield for an incandescent gas mantle. Complete Specification. Feb. 27.

4471. J. C. Hall, H. C. A. Dance, and A. R. Hall. Improvements in apparatus for the manufacture of acetylene gas. Feb. 28.

4548. F. J. Stedman. Improvements in and relating to apparatus for the production of oxygen gas. Feb. 29.

4674. S. S. Bromhead.—From A. Niel. A self-regulating gas generator. Complete Specification. March 2.

4823. M. Horwitz. An improved vaporiser for liquid combustibles. March 3.

4980. W. Wheatley and G. Kros. Improvements in apparatus for the production of carburetted water-gas. March 5.

5051. R. G. Shadbolt and J. Wilson. Improvements in the method of and means for enriching coal-gas. March 6.

5085. M. W. Richardson-Bunbury and F. C. Dew. A mantle protector for incandescent gas light. March 6.

5118. H. C. B. Forester. Improvements in and apparatus for the production of consolidated fuel from fine coal or coal dust. March 6.

5133. L. Chapman. Improvements in the separation and obtainment of oxygen from atmospheric air. March 7.

5134. L. Chapman. Improvements in and in the preparation of material for use in the retorts of furnaces in obtaining oxygen from atmospheric air. March 7.

5279. G. Ragot. Improvements relating to the production of acetylene gas and to the utilisation of the same for lighting purposes. Complete Specification. March 9.

5291. A. Kitson. Improvements in apparatus for the manufacture of gas, partly applicable to other purposes. March 9.

5336. R. Lavender and W. Tice. Appliances for increasing the illuminating power of gas under combustion. Complete Specification. March 10.

5368. J. H. H. Duncan. Improvements in incandescent gas burners. March 10.

5375. E. T. Turney. Improvements relating to the generation of gas and to apparatus therefor. Complete Specification. Filed March 10. Date applied for Feb. 1, 1896, being date of application in United States.

5423. P. J. Schlicht. Improvements in and relating to art of and apparatus for producing combustion. Complete Specification. March 10.

5624. E. Farnsworth. Improvements in apparatus for the manufacture of gas. Complete Specification. Filed March 12. Date applied for Aug. 12, 1895, being date of application in United States.

5686. S. Hersey, and Kirkham, Hulett, and Chandler, Ltd. Improvements in apparatus for washing, scrubbing, and purifying gas. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

5860. G. Haycraft. Apparatus for use in the manufacture of artificial fuel. Feb. 26.

6690. A. Besson. Incandescence gas burners. March 4.

7502. W. Thomson and H. Smith. Manufacture of fuel. Feb. 26.

8746. A. R. Newman and J. M. Somerville. Manufacture of illuminating gas. March 4.

9538. S. Cutler. Improvements in fittings for water-gas washers. March 11.

15,890. E. Rohrbach. Gasifying and increasing the heating power of the gases of easily inflammable liquids. March 11.

23,235. S. Pitt.—From La Société Internationale du Procédé A. Seigle. Improvements in apparatus for treating heavy hydrocarbons by means of heat, especially applicable for distillation and the manufacture of oil-gas. March 11.

1896.

1116. F. Rossbach-Rousset. An improved process and apparatus for the production of acetylene gas for acetylene gas-lighting. Feb. 26.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATION.

4598. A. Schmidt. Improvements in and apparatus for the dry distillation of wood, wood waste, and the like. Complete Specification. Feb. 29.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

3966. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new phthaline colouring matter. Feb. 24.

5044. I. Levinstein and Levinstein, Ltd. Manufacture or production of new colouring matters. March 6.

5668. T. R. Shillito.—From J. R. Geigy and Co. Improvements in the manufacture of greenish-blue colouring matters or dyes of the malachite green series. March 6.

5090. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of safranin azo dye-stuffs soluble in water. March 6.

5268. O. Imray.—From The Society of Chemical Industry in Basle. Process for the transformation of the thio-sulphonates of the indamines and indo phenols into thiozine colouring matters. Complete Specification. March 9.

5585. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of iodo derivatives of oxybenzoic acids. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

5114. O. Imray.—From The Society of Chemical Industry in Basle. Manufacture of orange to brown colouring matters. March 18.

7665. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of colouring matters. Feb. 26.

8572. S. Pitt.—From L. Cassella and Co. Producing dis- and poly-azo dye-stuffs from γ -amidonaphtholsulpho acid. March 4.

8645. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Improvements in the production of new sulphonic acids derived from naphthalene and of colouring matters therefrom. Feb. 26.

8988. P. A. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of chemical compounds and dye-stuffs derived from phenolic bodies. March 11.

8989. P. A. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of chemical compounds suitable for the production of colouring matters in bulk or on fibre. March 11.

9103. G. W. Johnson.—From Kalle and Co. Manufacture of amido bases and amido sulpho acids belonging to the naphthalene series and of colouring matters therefrom. March 11.

9454. G. W. Johnson.—From Kalle and Co. Manufacture of fast azo colouring matters especially adapted for dyeing on wool. March 11.

9645. S. Pitt.—From L. Cassella and Co. The manufacture of new azo dyes and of materials for producing the same. March 18.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

3517. J. R. Hoyle and H. Colburn. Improvements in back-washing machines for use in the treatment of wool or other fibrous substances. Feb. 17.

5532. C. E. Puller and A. Biermann. Improved process for loading silk and silk waste. Complete Specification. March 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8642. W. P. Thompson.—From R. C. L. E. de Swarte and J. M. E. Doumer. Improved process and apparatus for retting and drying flax and other textile materials. March 11.

8858. S. Simon and R. Dux. Preparation of textile materials and fabrics. March 4.

16,766. W. Fairweather.—From E. Balatsch, C. Herold, and A. Bayer. Process for cleaning by chemical means combs and other wool and hair waste stained with pitch, tar, and other colouring material. March 4.

20,501. C. Geige. A new or improved process for the manufacture of chemically prepared pent fibres applicable to various useful purposes. Feb. 26.

23,882. W. G. Heys.—From G. Malard. Improvements in scouring and degreasing wool. Feb. 26.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

3830. W. Leach. Improvements in apparatus for dyeing fibrous material. Feb. 20.

3991. H. H. Lake.—From J. C. Blundell. Improvements in and relating to yarn-dyeing machines. Complete Specification. Feb. 21.

4449. J. W. Slater and J. Parkinson. See Class XVIII. B.

4538. E. Weldon. Improvements in machinery for ageing or oxidising aniline blacks on hosiery goods. Feb. 29.

4890. A. Ashworth. Improvements in fixing metallic mordants on fibres and fabrics. March 4.

5712. J. Barnes. The production of fast colours on animal fibre by the aid of oxide of titanium. March 14.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

3662. A. D. Delsenme. A new or improved process for the purification of carbonic acid gas passing from lime kilns and designed for liquefaction. Feb. 18.

3869. J. T. Conroy, F. Hurter, and J. Brock. Improvements in the manufacture of ferrocyanides from sulphocyanides. Feb. 20.

3987. W. P. Thompson.—From C. von der Linde. An improved process for obtaining acetic acid from pyroigneous salts. Complete Specification. Feb. 21.

4340. G. Munroe and J. W. Kelly. Manufacture of oxygen, hydrochloric acid, and other products. Feb. 26.

4407. J. F. Campbell and J. Keating. Improvements in apparatus for the concentration or rectification of sulphuric acid or other acids or liquors. Feb. 27.

4489. G. Craig. Improvements in obtaining alkali salts and apparatus therefor. Feb. 28.

4725. W. L. Wise.—From Solvay et Cie. See Class I.

4743. L. G. Paul. Improvements in the manufacture of nitrites of soda and potash. March 3.

5011. P. Duggan. Improvements in or relating to saturators for use in the manufacture of sulphur of ammonia. March 5.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6711. A. R. Scott and T. Henderson. Purifying acetates. Feb. 12.

7273. H. K. Baynes and The Chemical and Electrolytic Syndicate, Lim. Apparatus for the decomposition of alkaline nitrates. March 11.

7365. M. Schmeltzer and C. Aschman. Manufacture of a sulphuric alcohol and glycerin mixture, and its application for tanning or preparing leather. Feb. 26.

8342. J. Todd. An improved method of and apparatus for treating brine in the manufacture of salt. March 11.

8381. H. Bower. Manufacture of prussiates. March 4.

8425. H. E. Newton.—From The Farb. vorm. F. Bayer and Co. The manufacture or production of chemical compounds containing sulphur. March 4.

8669. H. W. Crowther, F. C. Rossiter, and G. S. Albright. Manufacture of cyanides. March 11.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

4093. G. H. Grundy and G. A. Lingard. Improved method or means of decorating tiles, plates, and other articles of ceramic ware. Feb. 24.

4189. F. Albrecht. An improved oven for burning or fusing lettering, designs, colours, and the like into or upon articles of glass, earthenware, and other glazed or enamelled goods. Feb. 25.

4350. M. E. Norris. Improved methods of preparing imitation coloured, frosted, or embossed ornamental glass of all kinds, whether ordinary or ground glass be used for such purposes. Feb. 27.

4945. F. Radcliffe. Improvements in furnaces suitable for use in the manufacture of glass. March 4.

5622. C. Mayer. Improvements in and relating to pottery-ware and like glaze firing-kilns. Complete Specification. March 12.

5761. C. Riessner, H. Riessner, E. Stellmacher, and R. Kessel. An improved manufacture of ceramic products. March 14.

5772. L. A. Garchey. Manufacture of ceramic stone objects by devitrification of glass. March 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6237. E. Bohm. Enamelled or glazed bricks and tiles. March 4.

8409. H. Emery and J. Emery. An improved construction of kiln for firing articles made of or from china, earthenware, and the like. March 4.

24,263. J. Badon. A new product for use in substitution of sheet glass for windows, engraved glass, painted glass, blinds, curtains, and other purposes. Feb. 26.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

3519. W. Wardle. Bituminous cement. Feb. 17.

3597. A. Hannemann and G. Boisly. Improvements in the process of manufacture of artificial asphalt. Feb. 17.

3799. W. P. Thompson.—From La Société Anonyme la Neo-Litho. Improvements in the manufacture of artificial stone and apparatus therefor. Feb. 19.

3800. W. P. Thompson.—From La Société Anonyme la Neo-Litho. Improvements in the manufacture of artificial stone. Feb. 19.

3972. S. Neffgen. Improvements in the manufacture of artificial stone. Feb. 21.

3985. A. Clery. A new or improved cement. Complete Specification. Feb. 21.

3993. W. F. Williams. Artificial stone for building purposes. Feb. 21.

4270. K. Erdmann. Improvements in artificial stone blocks, slabs, or tiles for building purposes. Feb. 25.

4918. R. A. Chesebrough. Improvements in the art of manufacturing cement. Complete Specification. March 4.

4943. W. Ycullen. Improvements in the construction of fireproof buildings. March 4.

5386. O. Kleinberger. Improvements in building bricks. Complete Specification. March 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

7622. R. Walker. Construction of artificial stone slabs, bricks, tiles, and the like. March 4.

9210. S. Jorgensen. Manufacture of slag-cements. Feb. 26.

9283. W. H. Metcalfe and F. B. Wrightson. The manufacture of an improved artificial stone and the manufacture of various articles therefrom. March 11.

10,207. S. G. Bird and J. Wright. Manufacture of cement concretes. March 18.

21,293. F. W. Golby.—From F. Schmeisser. Manufacture of cement or plaster compounds. Feb. 26.

1896.

643. A. W. Perriman and W. Owen. Improvements in or relating to the manufacture of steps, building or monumental slabs, and other articles of artificial stone, asphalt, or the like, and apparatus therefor. March 18.

2746. E. Buchholtz. Improvements in or connected with paving and paving blocks. March 11.

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

3603. J. B. Torres. Improvements in or relating to the extractions of manganese from ores and the like, and preparations of compounds therefrom. Feb. 18.

3918. A. J. Boulton.—From H. Eichbaum. Improvements in or relating to the recovery or separation of metals from their ores. Feb. 20.

4073. A. J. Boulton.—From J. T. Penny and W. H. Richardson. Improvements in the process of triturating and amalgamating ores, and in apparatus therefor. Feb. 22.

4165. E. L. Oppermann. A new or improved process for amalgamating and extracting gold or other suitable metals from dry crushed ore. Feb. 25.

4326. J. H. Dickinson. Improvements in the manufacture of armour plates. Feb. 26.

4329. W. L. Holms and T. Dobbie. Method of precipitating gold and silver from cyanide solutions. Feb. 26.

4422. The Exploring and Gold Mining Association, Ltd. From S. H. Emmens. A process for recovery of zinc from blende ores. Feb. 27.

4667. F. F. Barnes and F. Campbell. Soldering of aluminium or metals alloyed with aluminium. March 2.

4776. W. H. Bailey. Improvements in and relating to furnaces for heating metal. Complete Specification. March 3.

4899. J. C. Bull. Improvements in alloys. March 4.

5071. C. W. Robinson. A new tool steel and means for producing the same. March 6.

5087. T. Parker and J. Pullman. Improvements in the treatment of sulphide ores. March 6.

5123. W. H. Duncan and R. Duncan. Improvements in extracting gold, silver, copper, and other metals from earthy matter; also in separating precious stones from the earthy matter in which they are found. March 7.

5260. F. Ellershausen. Improvement in the reduction of refractory ores. March 9.

5265. J. H. Dickinson. Improvements in the manufacture of armour plates. March 9.

5358. L. Pszezolka. Improvements in the Bessemer or Thomas process for the treatment of low qualities of crude iron. March 10.

5533. J. B. Torres. Improvements in or relating to the extraction of gold and other metals from ores and the like. March 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

4004. J. Mactear. Improvements in the extraction of precious metals from their ores or from compounds containing the same. March 4.

9081. H. C. S. Dyer. Manufacture of iron and steel by which sulphur is eliminated. March 18.

9610. W. P. Thompson.—From H. Schaaf. An improved thin liquid substance for case-hardening iron. March 18.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

3712. F. Mousterde, C. Chavant, and J. George. Improvements in electro-accumulators. Feb. 18.

4345. J. H. Dunn and R. G. E. Dalrymple. Improvements in the production of gas by means of electricity. Feb. 26.

4406. E. A. McLachlan. Improvements in and connected with electrical storage batteries. Feb. 27.

4434. F. King. Improvements in or connected with moulds for use in the manufacture of secondary battery plates or supports. Feb. 27.

4937. E. Clark, W. Clark, and F. King. Improvements in plates, grids, or supports for the elements of secondary batteries. March 4.

5098. G. B. Baldo. Improvements in electrolytic processes and apparatus therefor. Complete Specification. March 6.

5253. S. O. Cowper-Coles. Improvements in or connected with the electro-deposition of metals. March 9.

5263. H. A. V. Wirth. An improved process for the electro-plating or metallisation of wood. March 9.

5274. A. S. Smith, T. A. Smith, R. J. Smith, S. Smith, and T. Deakin. Improved apparatus for the electro-deposition of metals. March 9.

5506. P. F. Ribbe. Improvements in electric accumulators. Complete Specification. March 11.

5584. A. Cohen. Improvements relating to the use and treatment of carbon in electro-chemical or electrolytic processes, and to apparatus therefor. March 12.

5616. A. E. Peyrusson. Improved electrolytic processes and apparatus. March 12.

5673. A. S. Elmore.—From J. O. S. Elmore. Improvements in apparatus for refining metals by electrolysis. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

4660. A. Hiorus. Electro-deposition of iron on copper or other metallic surfaces. March 11.

7315. W. B. S. Barber-Starkey. Electrical storage batteries. Feb. 26.

8081. A. Schauschiff. Improvements in the active material for secondary and primary batteries. March 4.

8728. J. G. A. Rhodin. Improvements in plates for secondary voltaic batteries. March 11.

8905. C. L. R. E. Meoges. Primary and secondary galvanic batteries. March 11.

10,792. W. Elliott. An improved dry battery for electrical purposes, and material for packing same. March 11.

15,592. M. Ekenberg. Manufacture of perfumes. March 11.

24,172. A. C. Iwanowski. Improvements in or connected with galvanic batteries. Feb. 26.

1896.

475. W. C. Bersey. Electric accumulators. March 11.

780. H. Leitner. A new or improved method of manufacturing electrodes for secondary electric batteries. March 18.

1575. Siemens Brothers and Co., Limited.—From Siemens and Halske. A process for the electrolytic production of zinc from its ores. March 4.

XII.—FATS, OILS, AND SOAP MANUFACTURE

APPLICATIONS.

4137. A. G. Brookes.—From H. T. E. Kirkpatrick. A new or improved method of treating fatty acids. Feb. 24.

4138. A. G. Brookes.—From H. T. E. Kirkpatrick. A new or improved method of manufacturing fatty acids and their salts. Feb. 24.

4139. A. G. Brookes.—From H. T. E. Kirkpatrick. A new or improved method of manufacturing stearic acid. Feb. 24.

4140. A. G. Brookes.—From H. T. E. Kirkpatrick. A new or improved method of bleaching oils, fats, and similar substances. Feb. 24.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8814. W. P. Thompson.—From J. B. Okie. An improved process for making tormentil soap by the cold process. Feb. 26.

23,159. J. F. Lester and A. Riccio. Apparatus for separating oleaginous matter from a solvent. Feb. 26.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

APPLICATIONS.

3580. H. H. Lake.—From O. Leproux. An improved varnish, chiefly intended for protecting books from the attacks of insects. Feb. 17.

3725. R. McKenzie. Colours. Feb. 18.

3906. W. Hampe and C. Schnabel. Improvements in the manufacture of zinc oxide. Feb. 20.

4141. C. H. Owen. Artistic sugar paint. Feb. 24.

4249. W. P. Thompson.—From C. S. Bailey. Improvements in compositions or compounds for removing paint. Complete Specification. Feb. 25.

4373. J. Bradley. Improvements in the manufacture of spirit varnish. Feb. 27.

4942. A. Duval. Process for giving surfaces a phosphorescent coating. March 4.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8478. T. Lowe. Improvements in non-corrosive paint to resist the action of heat and atmospheric influence. March 4.

8915. H. Fleming. Manufacture of varnish. March 11.

24,224. L. Knoche. Improvements in the manufacture of an oil and of a varnish prepared therefrom. March 4.

1896.

2201. A. J. Boulton.—From L. P. Converse. Improvements in materials or compounds for waterproofing fabrics. March 11.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

3518. R. D. Bailey. Improvements in tanning for the production of leather. Feb. 17.

3715. J. W. Peirson and F. A. T. Moor. Improvements in the art or process of treating skins. Complete Specification. Feb. 18.

3773. J. B. Scammell and E. A. Muskett. Improvements in the manufacture of leather. Feb. 19.

3901. F. B. O. Hawes. Improvements in the treatment of leathers for their better preservation and surface preparation. Feb. 20.

4057. F. B. O. Hawes. Improvements in the manufacture of material suitable for belting, carding cloths, soles of boots, and like uses. Feb. 22.

4199. J. Hall. Improvements in machinery for treating skins, hide leather, and like substances. Feb. 25.

5644. J. A. McIntosh. An improved method of treating hides and skins, &c. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

7365. M. Schmeltzer and C. Ascham. See Class VII.

8215. H. Schmiedel. Manufacture of imitation or artificial leather. March 11.

8960. O. Thiele and J. Stocker. Manufacture of artificial leather. March 11.

XV.—AGRICULTURE AND MANURES, Etc.

APPLICATIONS.

4946. A. A. Yvert and C. J. Yvert. Improvements in the manufacture of superphosphates. March 4.

5495. J. S. Wallace and J. Castell-Evans. Improved processes for the production of nitrogenous and other substances. March 11.

COMPLETE SPECIFICATION ACCEPTED.

1895.

14,143. G. A. Macintire. An improved odourless liquid manure. March 11.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

3565. M. Zahn. Improvements in sugar refining. Complete Specification. Feb. 17.

3613. E. Shaw. Improvements in and relating to boiling sugar and other syrups. Feb. 18.

3890. E. Bert. Improvements in or relating to the purification of saccharine liquids or syrups. Feb. 20.

4560. D. N. Bertram. Improvements in and relating to strainers for treating paper pulp, separating fibrous materials from starch, and like purposes. Feb. 29.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

4415. E. Lofts and G. H. R. Lubbs. Improvements in or relating to brewing. Feb. 27.

4598. H. H. Lake. From J. Effront. Production of yeast. March 11.

COMPLETE SPECIFICATION ACCEPTED.

1896.

2587. A. Myers. Improvements in processes of manufacturing fermented and distilled liquors. March 11.

XVIII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, AND DISINFECTANTS.

APPLICATIONS.

A.—Chemistry of Foods.

3833. J. Dunn and W. Dunn. Improvements in treating lentils, peas, and other leguminous vegetables to obtain new alimentary products. Feb. 20.

3933. P. Walsh. Walsh's new and improved method of curing and preserving and flavouring oxen, cattle, pigs, sheep, fowls, and fish for human food and other purposes. Feb. 21.

5218. G. M. Keevil. An improved method of preserving provisions in the fresh state. March 9.

5749. D. Finkler. A process for the preparation and extraction of albuminous substances from animal or vegetable mixtures and products. March 14.

B.—Sanitary Chemistry.

4449. J. W. Slater and J. Parkinson. Improvements in dealing with foul and waste effluents from bleach works and the like, and in means therefor. Feb. 28.

5655. J. T. Wood and J. A. Brodie. Improvements in and relating to the treatment of sewage, and in apparatus therefor. March 13.

C.—Disinfectants.

5119. W. Hanlon. A combined deodorising, disinfecting, detergent, and saponifying mixture. March 6.

5381. P. O'Dowd. Composition for utilising and disinfecting sewage matter. March 10.

5705. J. N. Spence. A new or improved insecticide. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1895.

4489. A. Dubuisson. Manufacture of margarines and natural butters and apparatus therefor. March 11.

5776. A. Eckardt. A new process of torrefying coffee. March 18.

1896.

2709. B. Dunn and W. Dunn. Improvements in treating barley to obtain a new alimentary product. March 11.

3130. W. P. Thompson.—From The New Process Food Co. Improvements in and relating to granulated or powdered food extracts. March 18.

B.—Sanitary Chemistry.

1895.

8256. T. Royle. An improved method of purifying water. March 4.

C.—Disinfectants.

1895.

8575. J. J. A. Trillat. Improvements in vaporising apparatus, more especially for use in producing vapours of formic aldehyde or formal for disinfecting purposes. March 18.

9535. I. S. McDougall and J. T. McDougall. Improvements in insecticides. March 18.

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

4497. O. Tietze. Process for increasing the suppleness or pliability of paper. Feb. 28.

4560. D. N. Bertram. See Class XVI.

4713. C. F. Cross. Improvements in the manufacture of alkali cellulose. March 2.

5665. J. Bradley. Improved method of utilising the sludge or waste products from paper mills. March 13.

COMPLETE SPECIFICATION ACCEPTED.

1896.

2388. F. W. Hall. Improved apparatus for straining paper pulp and the like. March 11.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

3555. J. C. Richardson. Improvements in or relating to the manufacture of camphors or like compounds. Feb. 17.

3706. J. Y. Johnson.—From Vereinigte Chininfabriken Zimmer and Co. Improvements in the manufacture and production of a pharmaceutical product. Feb. 18.

3791. G. B. Ellis.—From La Soc. Chimique des Usines du Rhone anet. G. P. Monnet and Cartier. The manufacture of new compounds from pbenetidine and its homologues. Feb. 19.

3998. A. J. Boulton.—From G. Barthel. Improvements in or relating to a process and apparatus for the preparation of aldehydes. Complete Specification. Feb. 21.

4544. H. Archer. Digestine. Feb. 29.

4991. J. Y. Johnson.—From Vereinigte Chininfabriken Zimmer and Co. The manufacture and production of new pharmaceutical preparations. March 5.

5293. W. Gray. An improved process and apparatus for the manufacture of methyl aldehyde (formic aldehyde). March 9.

5490. O. Murray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of di-iodo-salicylic acid. March 11.

5672. E. Langheld. Ozone compounds for medicinal purposes. Complete Specification. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

5255. O. Porsch. Processes of and apparatus for making pure acetone. March 18.

1896.

21. W. Majert. Manufacture or production of vanillin. March 4.

XXI.—PHOTOGRAPHIC MATERIALS AND PROCESSES.

APPLICATIONS.

3765. J. Martyn. An improved method of producing photographic prints. Feb. 19.

3902. S. D. Rowland. Improvements in skiagraphy or photography by means of Röntgen's x-rays. Feb. 20.

3997. I. N. V. Bablon. Improvements in photographic plates. Feb. 21.

4023. A. W. Porter. Improvements in the manufacture of high vacuum bulbs for photographic purposes. Feb. 22.

4244. C. D. Ahrens. A method of obtaining light of any desired colour for the purposes of chromo-photography without the use of coloured glass screens. Feb. 25.

4286. C. O. Weber. Improvements in the manufacture of photographic plates of high sensitiveness to dark rays and radiations. Feb. 26.

COMPLETE SPECIFICATION ACCEPTED.

1895.

9438. F. Hrdliczka-Csiszar. Improved printing silver nitrate paper for photographic purposes and process of preparing same. March 18.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

4509. W. Greaves and E. M. Hann. Improvements in or relating to explosives. Feb. 28.

4714. M. Bals. Process for rendering amorphous phosphorus applicable as substitute for the yellow phosphorus for matches, primings, and the like. Complete Specification. March 2.

5432. O. Nagel. Improvements relating to the production of nitrocellulose compounds. March 10.

5575. A. Pain. Improvements in ships' signal lights, rockets, and similar fireworks. March 12.

5687. W. P. Thompson.—From B. T. Steber and W. E. Cook. Improvements in apparatus for making lucifer matches or the like. Complete Specification. March 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

9419. W. Theodorovic. Production of explosives from reduced and nitrated cellulose bodies. March 18.

2575. H. H. Lake.—From Fried Krupp Grusonwerk. An improved process and apparatus for the manufacture of explosives. March 11.

THE JOURNAL

OF THE

Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 4.—VOL. XV.]

APRIL 30, 1896.

Non-Members 80/- per annum; Members
21/- per Set of extra or back numbers;
Single Copies (Members only) 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
Dr. W. H. Perkin, F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1889.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.
Dr. T. E. Thorpe, LL.D., F.R.S.	1894—1895.

COUNCIL FOR YEAR ENDING JULY, 1896.

President: Thos. Tyrer.

Vice-Presidents:

<i>Sir F. A. Abel, Bart., F.R.S.</i>	<i>T. Fairley.</i>
<i>Horace T. Brown, F.R.S.</i>	<i>Boverton Redwood.</i>
<i>John Calderwood.</i>	<i>Sir H. E. Roscoe, M.P., F.R.S.</i>
<i>Chas. Dreyfus.</i>	<i>E. C. C. Stanford.</i>
<i>Dr. A. Dupré, F.R.S.</i>	<i>Dr. T. E. Thorpe, LL.D., F.R.S.</i>
<i>Sir John Evans, K.C.B., F.R.S.</i>	<i>Prof. W. A. Tilden, F.R.S.</i>

Ordinary Members of Council:

<i>J. S. MacArthur.</i>	<i>C. C. Hutchinson.</i>
<i>C. A. Fawcitt.</i>	<i>Ivan Levinstein.</i>
<i>R. Le Neve Foster.</i>	<i>Sir Robt. Pullar.</i>
<i>W. Douglas Herman.</i>	<i>G. N. Stoker.</i>
<i>David Howard.</i>	<i>Wm. Thorp, B.Sc.</i>
<i>Prof. A. K. Huntington.</i>	<i>Frank Wilson.</i>

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, B.

Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members whose names are placed in italics in the list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. Edward Schunck, F.R.S., has been nominated to the office of President; and Mr. Thomas Tyrer has been nominated Vice-President under Rule 11.

Prof. A. K. Huntington, Mr. A. H. Mason, and Mr. G. N. Stoker have been nominated Vice-Presidents under Rule 8; and the Treasurer and Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18:—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

The Annual General Meeting will be held in London on the 15th, 16th, and 17th July next. A provisional programme is enclosed with this number of the Journal. Tickets of Membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

COLLECTIVE INDEX.

A collective index, embracing the whole Journal from the Proceedings of the First Annual General Meeting, 1881, to the close of 1895, is now in preparation, and will be ready in the current year. It will contain both a subject-matter and authors' names portion and will be a volume of about 500 pages, uniform in size with the Journal.

The prices will be as follows:—

To Members (see Rules 25 and 27) who make application with remittance, not later than June 30, 1896.....	Each copy	5s.
To Members (see Rules 25 and 27) who make later application; Libraries, Corporations, and Exchanges on the Society's List, and Past Members (see Rule 30)	Each copy	10s.
To Subscribers	"	12s. 6d.
To others.....	"	15s.

MEMORIAL TO THE LATE PROF. HUXLEY, F.R.S.

This Memorial will take the form of a statue to be placed in the Museum of Natural History, and a medal in connection with the Royal College of Science, while the surplus will be devoted to the furtherance of biological science. Donations towards the fund should be sent to Mr. G. B. Hower, Hon. Sec. Huxley Memorial Committee, Royal College of Science, South Kensington, S.W.

MEMORIAL TO THE LATE PROF. PASTEUR.

At a meeting of the Provisional Committee of the British Section of the Pasteur International Memorial, held on March 21st last, Sir Joseph Lister in the chair, it was unanimously resolved, "That application be made for subscriptions towards the erection of a monument to Pasteur in Paris from persons in the United Kingdom, India, and the Colonies, interested in science and the various industries which have been benefited by Pasteur's labours." An Executive Committee was formed consisting of Sir Joseph Lister, Sir John Evans, Sir Henry Roscoe, Dr. Thorne Thorne, and Prof. Percy Frankland (Hon. Sec.). Subscriptions may be sent to Sir John Evans, who will act as Hon. Treasurer, at the Royal Society, Burlington House, W.

ADDRESS TO PROF. CANIZZARO.

At a meeting of Council held on March 23rd it was unanimously resolved to present an address of congratulation to Prof. Canizzaro on the attainment of his seventieth year of age, which occurs on July 12th next. The drafting of the address was placed in the hands of the Hon. Foreign Secretary of the Society.

INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

This Congress will be opened in Paris, possibly at the Hotel "des Agriculteurs de France," on Monday, July 27th next, and will continue for about ten days. All enquiries and adhesions should be addressed to the General Secretary of the Conference, 156, Bd. Magenta, Paris.

LIST OF MEMBERS ELECTED 23rd APRIL 1896.

- Boot, John C., Brooklyn Distilling Company, Kent Avenue, Brooklyn, N.Y., U.S.A., Chemist.
 Burford, Samuel F., Eastleigh, Queen's Road, Leicester, Analytical Chemist.
 Crawford, Alex., 113, Fenchurch Street, E.C., Chemical Merchant.
 Crosfield, George R., Walton Lea, Warrington, Soap Manufacturer.
 Eimer, August, 220, East 19th Street, New York, U.S.A., Druggist.
 Graham, W. Harry, 115, Broadway, New York, U.S.A., Industrial Chemist.
 Hart, Bertram, c/o Tennants and Co., Clayton, Manchester, Analyst.
 Humphrey, H. A., West View, Winnington, Northwich, Departmental Manager of Chemical Works.
 Job, Robt., 430, Franklin Street, Reading, Pa., U.S.A., Analytical Chemist.
 Jones, G. Cecil, Basingstoke Ironworks, Basingstoke, Works Chemist.
 Kohstamm, E. H., 44, West Broadway, New York, U.S.A., Colour Maker and Importer.
 Manoukian, Wahan, 173, Patatine Road, Didsbury, Manchester, Analytical Chemist.
 Mather, Wm., Salford Ironworks, Salford, Manchester, Chemical and Mechanical Engineer.
 Mayfield, A. S., c/o S. Tudor and Co., Lead Works, Hull, Analyst.
 Queeny, John F., c/o Merek and Co., New York, U.S.A., Chemical Merchant.
 Reid, Robt., Chestnut House, Horbury, near Wakefield, Student.
 Saunders, Walter M., Olneyville, R.I., U.S.A., Analytical Chemist.
 Shimomura, K., Harris School of Science, Kyoto, Japan, Professor of Chemistry.
 Smith, Harold Wilson, 4, Northbrook Road, Lee, S.E., Chemical Engineer.
 Sunderland, Arthur, 2, Rothesay Road, Luton, Beds, Teacher of Chemistry.
 Wyckoff, George H., c/o Curtice Brothers Co., Rochester, N.Y., U.S.A., Chemist.

CHANGES OF ADDRESS.

- Barnes, E. A., 1/o Hayle; 194, Hammersmith Road, London, W.
 Barton, G. E., 1/o Hatfield; Flint Glass Works, Millville, N.J., U.S.A.
 Benjamin, Dr. M., 1/o New York; Smithsonian Institution, Washington, D.C., U.S.A.
 Beveridge, Jas., 1/o Sweden; Linelle, Old Road West, Gravesend.
 Briggs, J. F., 1/o Wandsworth; Sakri, near Darbhanga, Behar, India.
 Brock, John, 1/o Liverpool; Gwern-Tyno, Colwyn Bay, North Wales.
 Claus, W. H., 1/o Fallowfield; 31, Mandeth Road, Withington, Manchester.
 Clemes, J. H.; Journals to c/o G. H. Alexander, 83, Lordship Road, London, N.
 Crawley, A. H., 1/o Schlader; 27, Chatsworth Avenue, Aintree, Liverpool.
 Davis, H. J., 1/o 45; 65, Wall Street, New York, U.S.A.
 Dixon, W. H., 1/o Wingfield; Shola, Selsdon Road, Wanstead, E.
 Dott, D. B., 1/o South Canongate; c/o J. F. Macfarlan and Co., 93, Abbey Hill, Edinburgh.
 Dowson, J. E., 1/o Great Queen Street; 39, Old Queen Street, Westminster, S.W.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman: R. Messel. Committee: W. J. Dibdin, R. J. Friswell, D. Howard, B. E. R. Newlands, B. Redwood, and T. Tyrer.*

SESSION 1895-96.

May 4th.—Mr. E. J. Wall. "Chromatic Photography."

June 1st:—

Mr. W. Gowland. "Japanese Metallurgy." Part I.

Mr. S. Cowper-Coles. "The Electro-deposition of Zinc."

Meeting held Monday, April 13th, 1896.

MR. B. E. R. NEWLANDS IN THE CHAIR.

MOISTURE IN WOOD PULP.

BY R. W. SINDALL.

This subject very naturally divides itself into two sections, the one dealing with the question of atmospheric moisture, and the other with more practical considerations involved in sampling and testing.

The former point has been discussed at various times in the Journal of the Society, the most recent contribution on the subject being a paper by Messrs. Readman and Gemmell in 1893 (this Journal, 1893, 1005). These gentlemen studied the variation in moisture and in the weight of different wood pulps caused by altered conditions of atmospheric humidity, which conditions were obtained by artificial means, viz., the more or less complete saturation of the air from steam obtained by boiling water in an open vessel, in order that the range of humidity might be as large as possible.

The general conclusions arrived at, as the result of observations extending over a few weeks, seemed to point to an average of 10 per cent. of moisture as the amount most likely to represent the normal condition of wood pulp in an air-dry state—mechanical giving a somewhat higher figure, sulphite a lower figure.

This variation in the weight of pulp, consequent on the increase or decrease of the saturation of the air, had also received considerable attention in the laboratory of the Daily Chronicle Paper Mills during the same year, 1893; but, unfortunately, the observations recorded were not sufficiently numerous for the purpose we had in view—the discovery of some law establishing a definite relation between the air-dry weight of pulp and atmospheric moisture.

We accordingly repeated the investigation on a larger scale in the hope of (1) accurately deciding the air-dry weight of wood pulp for normal atmospheric conditions common to this country; (2) obtaining the average weight for the whole period of observation, together with the average humidity; (3) from these results to determine the law connecting these two variable quantities.

The conditions of the experiment were perfectly simple: the pulps were exposed in a room on the ground floor, with free access of air through an open window and door. No gas or fire was used during the whole period, and thus the pulp was only subject to the influence of the air in its natural state. The quantities originally weighed out were such that on reaching an approximate air-dry state the weight was about 100 grms., with two exceptions.

The following tabulated statement gives the actual condition of the pulp before daily observations were commenced:—

Pulps exposed to Air, but not absolutely dried beforehand.

Description.	Mark.	Amount Weighed out.	Conditions.	Receptacle used.
Mechanical	A. 1	300 grms. wet	Torn up fine	Wire cage.
"	A. 3	200 "	Thick sheets	"
"	B. 5	200 "	Torn up fine	Shallow tray.
Sulphate	C. 7	100 grms. dry	"	Wire cage.
Soda	D. 9	"	"	"
Sulphite dry	E. 11	"	"	"
"	E. 13	"	"	Shallow tray.
Sulphite moist	F. 14	300 grms. wet	"	Wire cage.
"	F. 16	200 "	Thick sheets	Shallow tray.

Pulps absolutely dried before being exposed to Air.

Mechanical	A. 2	200 grms. wet	Torn up fine	Wire cage.
"	A. 4	"	Thick sheets	"
"	B. 6	"	Torn up fine	"
Sulphate	C. 8	100 grms. dry	"	"
Soda	D. 10	"	"	"
Sulphite dry	E. 12	"	"	"
Sulphite moist	F. 15	200 grms. moist	"	"

In this way, the influence of the high temperature on the sensibility of the pulp to atmospheric changes could easily be studied.

It should be noticed that the same samples were used during the whole investigation—a fact which ought not to be overlooked—and, in order to check the results, the contents of each receptacle were carefully turned out every three months, the cages and trays cleared and dusted, and the counterweights tested. The dust which accumulated during the period was duly ascertained, but proved to be a negligible quantity, while the possibility of error in weighing was reduced to a minimum by the use of receptacles exactly equal in weight, and balanced during the operation of weighing by a constant counterpoise.

Before daily readings were properly commenced, the whole of the samples were freely exposed for one month, in order that the moist pulps might be deprived of all excess moisture, and that the absolute dry pulps might absorb all that was possible, after which, for 12 months, the readings were taken practically every day, and included the exact weighing of the pulps to within 0.02 grm., together with the observations of the hygrometric conditions of the air as recorded by an ordinary dry and wet bulb hygrometer.

No useful purpose would be served in giving the details of the results obtained, so that in order to avoid a multiplicity of figures, which would only tend to confusion, the following tables have been constructed, in which all the records necessary for our object are presented.

Instead of giving the figures for each of the 16 samples, the readings have been reduced to nine columns by taking the average results for duplicate pulps exposed under precisely similar conditions.

At the headings of the respective columns the word "air" may be taken to mean that the figures refer to pulps which have been allowed to get dry by simple exposure to air, while by "abs.," the contraction for "absolute," we may understand that the pulps were first dried to a constant weight at 100° C. before being placed with the samples.

With the exception of the pulps exposed in the form of thick sheets, the results recorded in every column represent the figures obtained as the mean of duplicate tests with different brands of pulp.

Table I. gives the average monthly results calculated from the daily observations taken during the period of 12 months. These results are all given in a form which at once reveals the air-dry weight of pulp containing 88 parts of absolute dry fibre—a method of expression which has its own advantages, and which will be appreciated by members who are more directly interested in this question of moisture in wood pulp, on account of the fact that the trade in this article is based upon the assumption that 88 parts of absolute dry pulp is equivalent to 100 parts of air-dry pulp, although quite recently contracts have been and are now

being made on the basis of 10 per cent. and not 12 per cent. moisture.

The various points of interest to be noticed in these tables are as follows:—

(1.) In every case the susceptibility of absolutely dried pulp to changes in the atmosphere is less than that of pulp which has not been submitted to the temperature of 100° C.

(2.) That the method of exposure, sampling, and drying exercises a material influence on the air-dry weight.

(3.) That the difference between the air-dry weight of mechanical and chemical pulps is too great to allow of a universal percentage of moisture being used, even for trade purposes.

(4.) That the average percentage of moisture for this period exceeds 12 per cent.

(5.) That the difference between the maximum and minimum observations is extraordinarily large.

(6.) That the relative humidity for each month and for the whole year is very high.

In discussing these points we may first notice the conditions of the experiment in regard to the atmosphere were decidedly abnormal.

TABLE III.

Relative Humidity.	Mechanical.	Sulphate and Soda.	Sulphite.
H.	Nos. 1, 2, 3, 4, 5, 6.	Nos. 7, 8, 9, 10.	Nos. 11, 12, 13, 14, 15, 16.
	Average.	Average.	Average.
51.4	99.03	95.98	96.53
60.00	100.04	96.42	96.85
65.30	100.42	96.91	97.45
77.20	102.24½	98.60	99.30
80.13	102.41	98.21	99.30
82.10	102.78	98.41	99.74
82.70	102.58	98.70	99.69
82.90	102.84	98.78	99.80
83.20	103.55	98.95	100.50
83.90	103.17	98.98	100.03
85.10	103.81	99.42	100.60
86.60	105.13	100.41½	101.63
87.50	104.55	99.92½	101.04
88.24	104.61	100.23	100.93
89.10	104.63	100.62	101.14
90.00	105.40	100.70	101.90
93.00	106.82	102.40	103.76

These figures cannot be accepted as perfectly accurate, because a certain amount of irregularity is very apparent in the columns, but this is not surprising when we consider the conditions of the experiment. On the one hand, the relative humidity is obtained from an instrument extremely sensitive to atmospheric changes, and which, in its usual form, cannot be read exactly to more than one-half a degree temperature; while, on the other hand, the air-dry weight is a quantity which only changes slowly and is extremely sluggish in alteration. Thus, while the weight can be determined easily at any given time, the relative humidity, measured by the readings taken the same hour, may only represent the degree of saturation producing that weight of pulp within about 5°. It is this fact which renders the whole investigation a difficult task, but this liability to error is reduced to a minimum by the use of the table, because the greater number of observations are average monthly results.

The precise value which may be attached to these figures can be readily ascertained by adopting the plan of plotting out a curve having the absolute dry weight for its ordinates and the relative humidity for abscissæ—a plan which not only detects irregularities in observation, but serves for their correction and enables interpolation of figures which have not been arrived at by observation, to be accomplished for the completion of the readings.

Average for 12 Months.	Official (normal), for all Years at Greenwich.	Experimental, for 1894.
Temperature of the air...	58.9	54.7
Wet-bulb thermometer ..	54.6	52.43
Difference	4.3	2.27
Calculated dew point	51.16	50.26
Relative humidity (saturation = 100).	75.20	85.10

In order to clearly indicate the relation of the air-dry weight to humidity, the tables given above must be reduced. The only difficulty which presents itself is the difference in the weight of pulp as determined on stove-dried and air-dried samples, as the method of drying the pulp to an absolute dry state before exposure influences the weight considerably. In following out the mode, however, for establishing the connection between these two qualities, we may for the present content ourselves with reducing tables I. and II. into another form showing the average results of the figures obtained, as in Table III.

The average results for the whole year, when the readings have thus been finally reduced to the smallest bulk, give as the air-dry weight of pulp which contains 88 parts of absolute dry fibre: mechanical 103.81, sulphate and soda 99.42, sulphite 100.60, the relative humidity being 85 per cent.

With the possibility of error in the degrees of humidity which has just been hinted at, it is somewhat remarkable to find that a regular curve can be drawn through the points of observation thus plotted out, in such a position that these

lie close to and evenly distributed about it—a fact which helps to confirm the accuracy of the table given above, and which must tend to enhance the value of the figures recorded. On this account, we need have no hesitation in using this

curve for the purposes mentioned at the commencement of of the paper, viz., the determination of the percentage of moisture in air-dry pulp under normal atmospheric conditions, and the discovery of some simple mathematical law connecting humidity and air-dry weight.

To do this, we require a fresh table in which the atmospheric conditions are represented by degrees of humidity increased by equal amounts, or in which the relative humidity forms a simple arithmetical progression. This is obtained from the curves drawn for the three classes of pulp, and is shown in Table IV.

TABLE IV.
Figures obtained from the Curves.

Relative Humidity H.	Air-dry Weight of Pulp.			Average difference for 5° H.	Constant r .
	Mechanical.	Sulphate and Soda.	Sulphite.		
50	98.95	95.90	96.35	0.26	..
55	99.30	96.10	96.60	0.33	1.25
60	99.70	96.35	96.95	0.42	1.27
65	100.20	96.65	97.40	0.52	1.24
70	100.80	97.05	97.95	0.68	1.30
75	101.60	97.60	98.65	0.82	1.22
80	102.50	98.30	99.50	1.13	1.35
85	103.75	99.35	100.60	1.52	1.34
90	105.25	100.80	102.20
					mean = 1.28

It is at once evident from this table that the increase in moisture does not follow the same law of arithmetical progression. The law connecting the two variable quantities, humidity and air-dry weight of wood pulp, may be expressed thus:—If the numbers representing humidity form a series in arithmetical progression, then the weight of wood pulp corresponding to those numbers produces a series of figures in geometrical progression, thus:—

$$\text{Humidity} = H, H + d, H + 2d, H + 3d, H + 4d,$$

$$\text{Weight} = W, W r, W r^2, W r^3, W r^4,$$

where $d = 5$, $r = 1.28$.

If the value of r be calculated separately for each class of pulp, the figures are 1.23, 1.31, 1.31, respectively.

The next matter which requires some consideration is the air-dry weight under normal atmospheric conditions and the percentage of natural moisture.

In this country the average normal degree of saturation, as taken at Greenwich Observatory, is 75 per cent., for which the weight of wood pulp, according to Table IV., is: mechanical, 101.60; sulphate and soda, 97.60; sulphite, 98.65; interpolated figures which agree with actual results (compare Table III.) giving as the percentage of moisture—

	Per Cent.
Mechanical.....	13.4
Sulphite.....	10.6
Sulphate and soda	9.6

For practical purposes, the percentage of moisture in air-dry mechanical pulp may be taken at 13 per cent., and in chemical pulps at 10 per cent.

This difference is too great to allow of a universal percentage of moisture being accepted for all pulps, and it is evident that it would be more desirable to adopt a different percentage for each of the two great classes of pulp as indicated.

The subject of sampling and testing for the purpose of arriving at the percentage of air-dry fibre present in a given consignment of wood pulp, is one of great importance to the paper trade.

The difficulty of determining the exact percentage is apparent when the several factors which control the result are taken into consideration, viz., (1) the large bulk of the raw material, (2) the influence of exposure to air, (3) the variation in the gross weight of the bales, (4) the differences in moisture between selected bales, (5) the method of drawing samples, and so on.

No uniform method of sampling has yet been decided on by paper-makers or analysts, owing to this fact—that each individual adopts some plan of his own as the one most likely to approximate the true percentage of air-dry pulp, without having, perhaps, any time or opportunity to compare with the methods of others.

In the ordinary routine work of the mill it is considered sufficient to make a few rough tests on the various brands of pulp, with a view of determining that the amount of air-dry fibre is, at least, fully equal to the quantity invoiced.

On the other hand, the utmost care is required in the event of a dispute arising from the possibility of an excess of moisture.

Usually 10 or 20 bales, according to the size of the consignment, are considered enough, but the more correct plan is to sample a given percentage by weight of the whole parcel, although of course such a rule may be modified by circumstances. If the pulp is a good brand, characterised by uniformity as to the gross weight and moisture of respective bales, then 20 or less may prove sufficient, even in a large delivery; whereas 60 or 70 bales may hardly be correct enough for a pulp exhibiting irregularity in moisture and weight. The analyst must be guided by the condition of the pulp.

In the selection of bales, it must be remembered that the air-dry weight of the parcel is calculated on the air-dry weight of the few bales tested. Hence it is important that these should be unbroken, clean and uniform in appearance, and taken from such parts of the stack which are not exposed to air. The difficulty of correct sampling is greatly increased if bales which have been unduly dried by air or wetted by water are chosen for this purpose. In the actual sampling of these selected bales, the most important part of the process is reached.

We propose to describe somewhat in detail the methods of testing adopted at the Daily Chronicle Paper Mills, and also some experiments carried out in the hope of determining what method may be considered as the most exact.

In the case of moist mechanical pulp, which arrives packed in 2-cwt. or 4-cwt. bales, the following plan has proved to be fairly reliable and quick:—

After the bales have been weighed, five sheets are sampled in each, from portions indicated in the diagram, viz., the centre sheet (3), sheets midway between the centre and the ends of the bale (2, 4), and two just beneath the extreme outside sheets (1, 5).

From each sheet small pieces are chipped out with the point of a knife, about four or five in number, and immediately dropped into a glass bottle. These pieces are chipped diagonally across the sheet, or across the length and width according to the subjoined figure:—

End view of the bale.

Plan of some of the sheets when sampled.

With dry sulphite packed as sheets in the bale, the five sheets are all first withdrawn from the bale, as indicated in the diagram, laid together, and small strips cut through the five, and bottled, from positions indicated, thus:—

Some very complete experiments have been carried out from time to time to determine the precise influence of the

various factors already hinted at, and as these are of interest and utility, we venture to give some of them.

The first and most important subject in connection with the question of moisture is the influence of the method of sampling.

Three experiments were carried out, and in each the actual method of sampling was different. All the experiments were repeated three or four times, and the total amount of pulp banded was about 9 tons of moist (mechanical).

The *modus operandi* for each experiment was as follows:—

(1.) Six bottles were labelled numerically in order for the reception of the samples.

(2.) The bales were carefully weighed and sampled according to a specified method, as given in Table B.

(3.) After sampling, the whole of the pulp for the test under consideration was placed in a tank and soaked overnight in hot water.

(4.) The soaked pulp was ground up in the edge runner, carefully weighed up in sacks, and again thoroughly sampled.

In Table A the conditions of each experiment are given in detail, while the methods of sampling are shown in Table B.

The object in passing the whole of the pulp from each test through the edge runner was to reduce the material into a uniform mass of particles which could be weighed and sampled in a totally distinct manner from the usual method as a further check.

TABLE A.

Experiment I.	Experiment II.	Experiment III.
Pulp had been in stock under cover two months.	Pulps had been stacked in the open about three weeks.	Pulp was tested immediately on delivery.
Five tests made on 15 cwt. moist pulp for each.	Four tests made with 12 cwt. moist pulp for each test.	Three tests made with 20 cwt. moist pulp for each.
Brand ABC	Brand X	Brand X.

TABLE B.

No. of Bottle.	I.	II.	III.
1	Small pieces from all five sheets.	Small pieces from sheets 1, 5.	Small pieces from sheets 1, 5.
2	Narrow strips cut diagonally from all five sheets.	Small pieces from sheets 2, 4.	Small pieces from sheets 2, 4.
3	Triangular pieces from centre of middle sheet only.	Small pieces from sheet 3.	Small pieces from sheet 3.
4	Triangular pieces from all five sheets.	Diagonal strips from sheets 1, 5.	Strips across length and width of sheets 1, 5.
5	Two special strips cut at right angles from centre sheet.	Diagonal strips from sheets 2, 4.	Strips across length and width of sheets 2, 4.
6	Two special strips cut at right angles from all five sheets, as in No. 5.	Diagonal strips from sheet 3.	Strips across length and width of sheet 3.

Note.—Samples were drawn from every sack of the pulp passed through the edge-runner, and six or seven tests made for moisture in all cases.

Plan of sheets, showing method of cutting.

It is impossible to deal here with the mass of figures which such a drastic method of treatment necessarily involved. The edge-runner test may be regarded as one of special value, as it reduced the whole pulp to a uniform condition, rendering the task of sampling a comparatively easy one.

After making all allowances for packing, loss in working, &c., the method which most closely approximated the results obtained by the use of the edge runner, was the cutting of narrow strips diagonally across all five sheets. At the same time, however, the method of chipping small pieces from all the sheets gave figures so close that it proved a reliable method, although the percentage was consistently a trifle higher.

From these results it would seem desirable to adopt as a universal method of sampling, the cutting of narrow strips diagonally across five sheets in every bale tested, or taking as a representative sample small pieces chipped from these sheets as indicated above.

It is easy to show that when a parcel is delivered in good condition, with uniformity in weight and moisture in the bales, a few bales are quite sufficient for a good test. In such cases 1 per cent. of the parcel will give a percentage of air-dry pulp very near the true result. On the other hand, a pulp which shows large variations in these matters may not give a satisfactory test even with 4 or 5 per cent. The following table is a striking illustration of this fact, showing that with a good uniform pulp, a small percentage is sufficient for the test:—

Table showing Percentage of Absolute Dry Pulp.

I. Mechanical Pulp in 100-lb. Bales. Very Uniform. 25 Bales to each Test.			II. Sulphite Pulp in 100-lb. Bales. Very Variable. 20 Bales to each Test.		
34.0	34.0	33.3	78.70	79.65	76.45
33.7	33.7	33.3	77.80	74.45	75.65
34.0	33.6	33.3	79.15	78.45	77.35
33.1	33.6	33.7	78.35		
33.6					
33.60			Mean		
38.18			Air-dry per cent.		
			77.60		
			88.18		

In the first case, if the mean be assumed as the most correct percentage, then the greatest error in any test is only 0.4 per cent., whereas in the second case the error is 3 per cent.

The details of these two instances, which are cases in actual practice, are as follows:—

The mechanical pulp was invoiced as 8477 bales = 378 tons 8 cwt. 3 qrs. at 40 per cent. air-dry pulp. Every 25th bale was taken, and, in all, about 340 bales out of the 8477 were actually tested, which means 4 per cent. of the whole delivery. The table conclusively shows that for a pulp in good condition any 25 bales would have given a test sufficiently accurate—a number equivalent to $\frac{1}{3}$ per cent. of the parcel.

With the sulphite pulp, the variation in moisture and weight rendered the task of testing exceedingly unsatisfactory. This pulp was invoiced as 1,562 bales = 70 tons 13 cwt. at 86.96 per cent. dry pulp, giving 61 tons 8 cwt. 2 qrs. air-dry weight. 200 bales, or 13 per cent. of the parcel, were tested in 10 lots of 20 bales each, the air-dry weight by the lowest test being 57½ tons, and by the highest 65½ tons. In this case 1 per cent. of the parcel is quite insufficient to ensure an accurate test.

The difficulties to be overcome in this subject of sampling could be multiplied and exemplified to almost any extent, but it would not serve any further purpose to prolong the paper beyond this point, seeing that the object of the writer has been accomplished in drawing attention to methods which might advantageously be adopted as suitable for universal application in sampling, and in suggesting some ideas for the elucidation of that oft-disputed question of atmospheric moisture.

DISCUSSION.

Mr. C. BEADLE said that about five years ago he had intended to undertake the task which the author had so successfully carried out, but the obstacles seemed insurmountable. He foresaw great difficulties which would prevent him from arriving at definite conclusions. First of all he thought of comparing the amount of moisture with the conditions of the atmosphere. Then it struck him that it would be far better to arrive at the mean condition of the atmosphere of the British Isles, and to then find the amount of atmospheric moisture for each kind of pulp under those conditions, and to establish that figure as the correct one to be allowed in each case. He saw the Secretary of the Meteorological Office, Mr. Robert Scott, who pointed out that it would be absurd to attempt to establish the mean conditions of the atmosphere by taking the mean readings of the different parts of the kingdom, so he was obliged to give up the idea. With regard to the difference between allowing the pulp to air-dry, and bone-drying a pulp and then allowing it to take up moisture, the author's figures fairly confirmed those he had obtained with regard to cotton. If cotton were dried and then exposed to the atmosphere it never returned to its original air-dry weight, but was always about $\frac{3}{4}$ per cent. short of that figure. His impression was that when a pulp was heated there was something besides water given off during the heating, and that the proper way to dry pulp was to put it in a desiccator, but for all practical purposes it would be sufficient to expose the pulp to 105° C. and to take the whole loss as being due to water.

Mr. DAVID HOWARD remarked that, although not strictly to the point, it was rather interesting that the average amount of hydration of cinchona bark was almost exactly 12 per cent. air-dried, as compared with cinchona bark dried at 170°.

Mr. W. CROWDER asked what was the exact object of the experiments, and whether the pulp was bought as dry, and varied in coming over to England, and so caused disputes between the pulp makers and purchasers.

Mr. W. F. REID said that he had had a little experience on one point, namely, that when pulp had been heated previously it did not absorb so much moisture as when not previously heated. Cotton contained resinous matter as well as fatty matter; and he also made some experiments with pulp derived from resinous woods, and found that when cotton or wood fibre was heated in a water-bath the resin seemed to enter the pores of the cellulose and diminished the absorption of moisture. When cotton was previously treated with petroleum ether, he found the experiment did not produce the same result. He thought the action was due to some resinous matter which still remained in the pulp, and therefore was greater in the mechanical wood pulp than in that treated with soda. With cotton waste on a manufacturing scale, he had found as much as 12 per cent. of moisture absorbed from the atmosphere.

Dr. H. SCHLICHTER asked how much allowance should be made for cotton. On the Continent the official figure was only eight; and cotton, which was almost pure cellulose, showed a much lower figure than flax or hemp; the proportion increased in proportion to the woody matter.

Mr. C. BEADLE wished to add that he had examined cotton rags and found the average figure to be 7.3 per cent. He had recently conducted a number of trials to determine the rate at which cotton recovers atmospheric moisture on exposure to the air, some with a desiccator and some dried at 105° C., and it depended very largely on the physical division of the cotton fibre. Complete fibres of cotton gained about 7 per cent. before becoming constant in weight. If reduced to one-twentieth of their original length then the gain in weight was only about three. He was disposed to think that the length of the wood fibre, and whether intact or divided, would have a large influence upon the amount of atmospheric moisture it would ultimately contain.

Mr. R. W. SINDALL, in reply, said that the custom in the paper trade with regard to the question was that the pulp was bought on the basis of 12 per cent. of moisture in air-dry pulp, but lately the paper makers had come to

the conclusion that the best way to word contracts was that the pulp should be first absolutely dried at 100° C. and the result calculated on the basis that 88 parts of dry fibre would give 100 parts of air-dry fibre. He had tried to ascertain the average percentage, as lately the struggle of the paper makers with the pulp makers had resolved itself into an attempt at lowering the percentage. Curiously enough, the mechanical section of the Scandinavian Wood Pulp Association had accepted 10 per cent., whereas it was evidently 13 per cent. at least for mechanical. If the air-dry percentage figures had been taken instead of the mean between air-dry and absolute dry, as in Table III., it would be higher still. The other point in dispute was as to the method of sampling. It made a very material difference which way the pulps were sampled. He agreed with the remark that, owing to the presence of resinous matter, the mechanical figure was higher than the chemical, although he could not quite understand why the soda pulp, which was not such a pure form of cellulose, contained a lower percentage of moisture than sulphite. The experiments would, no doubt, have been more interesting if he had also taken unsized papers in which the fibres were reduced in length, as it might then have been seen whether the length of fibre had any influence on the weight, and he also might have dealt with the samples of cotton at the same time, but it had not occurred to him.

A STUDY OF COMPARATIVE AFFINITIES IN THE CASE OF CERTAIN SALTS OF AMMONIUM AND WOOL. PART II.

(See also this Journal, 1896, pages 3—8, and 197.)

BY WATSON SMITH.

Otto N. Witt's Process for the Recovery of Hydrochloric Acid from Ammonium Chloride by the Aid of Phosphoric Acid.—Witt patented a process (Ger. Pat. 34,395) in which he proposed to decompose ammonium chloride by heating it with phosphoric acid. Hydrochloric acid is driven off at a lower heat, and on raising the temperature considerably, ammonia is subsequently expelled, and vitreous phosphoric acid left behind, which can be used over again for attacking a further supply of ammonium chloride. Jurisch has investigated this process and found that upwards of 99 per cent. of the HCl can be expelled at 300° C., if a large excess of phosphoric acid be employed. By heating the residue subsequently to about 400° C., about 63 per cent. of the NH_3 is expelled. When employing the residue over again, 86 per cent. of the total ammonia, according to Jurisch, can be driven off.

I have also investigated the above question some three years ago (Feb. 1893), and the following are my results:—Some ammonium phosphate, $(\text{NH}_4)_2\text{HPO}_4$, was first experimented with. On heating, it was found that this compound commenced to evolve ammonia at 300° C., but that to expel all ammonia a red heat was necessary. The phosphoric acid left in the crucible was heated with a little water and some ammonium chloride. Hydrochloric acid is easily evolved.

On adopting proportions of 4 equivalents of phosphoric acid to 1 equivalent of ammonium chloride, the mixture being placed in a platinum crucible fitted with a small glass dome, headed with bent tube, and the latter being connected with a vessel containing normal soda, and this vessel again with a water-vacuum pump,—the following quantitative numbers were obtained: 72 per cent. of hydrochloric acid expelled, and on further heating to dull redness and absorbing in normal hydrochloric acid, 61.5 per cent. of ammonia. Another experiment gave 83 per cent. of hydrochloric acid and 83 per cent. of ammonia. With a slight increase still of excess of phosphoric acid, 99 per cent. of HCl was expelled, and afterwards, on ignition of the residue, 75 per cent. of the NH_3 . Using the same phosphoric acid in a further trial with another similar quantity of ammonium chloride, 90 per cent. of the HCl was expelled, and thereafter 67 per cent. of NH_3 . In this latter case, however, the singular result was obtained of a volatilisation at the high temperature employed, of some of the phosphoric acid along with ammonia. It is known,

of course, that phosphoric acid at a red heat is volatilised, and so persistently does ammonia unite with this acid in presence of a large excess thereof, that the heat necessary to expel the latter portions of that ammonia is also sufficient to volatilise phosphoric acid. The rule, then, as to the great stability of ammonia in presence of large excess of sulphuric acid also holds good in the case of ammonia in presence of large excess of phosphoric acid (see this Journal, 1896, 5 and 7). The phosphoric acid now left, after the expulsion of 67 per cent. of ammonia, was used again for acting upon a further addition of NH_4Cl , when 81 per cent. of HCl, and this time only 60 per cent. of NH_3 , were driven off. It was found that in the heating process, when the latter portions of HCl were being expelled, NH_4Cl was also apt to sublime.

For the employment of phosphoric acid—the syrupy acid—on a manufacturing scale for the decomposition of ammonium chloride in connection with the ammonia-soda industry, the difficulty arises that unless a large excess of the acid be used, only a partial decomposition ensues with a bad yield of HCl, and yet when this condition of large excess of phosphoric acid is observed, the very condition is embraced under which only partial expulsion of the ammonia left behind in combination as phosphate, can be looked for. It has been already observed that so tenaciously is this ammonia held in combination in presence of excess of phosphoric acid, that the temperature required to expel the former, also drives off some of the latter. From a technical point of view, it therefore became interesting to inquire as to the action of phosphoric acid at such temperatures upon various materials. It was found that glass was attacked, and also both zinc and iron. If glass be attacked, it is pretty certain also that fire-brick and fire-clays would not escape. Platinum even is slightly attacked, but Dr. A. F. Furst informs me that silver is invulnerable to phosphoric acid, besides being at present a great deal cheaper than platinum.

To give an idea of results obtainable by employing the same phosphoric acid upon successive portions of NH_4Cl , the following experiments may prove interesting:—

15 grms. of syrupy phosphoric acid with 2 grms. of NH_4Cl , on heating, evolved 96 per cent. of the theoretically obtainable HCl. On further heating to dull redness, 26 per cent. of the NH_3 were recovered. Further additions of NH_4Cl were then made and the process repeated 7 times—

HCl.	NH_3 .
Per Cent.	Per Cent.
(1) 96	26
(2) 100	79
(3) 85	62
(4) 80	83
(5) 92	46
(6) 100	60
(7) 100	48

Mean of the 7 results = 93 and 58 respectively.

After 12 experiments in all, the platinum crucible had lost 0.007 gm. Experiment 1 will give a good idea of the tenacity of the hold the phosphoric acid has upon the ammonia under the conditions of excess named.

To the question, "What becomes of the missing hydrochloric acid in experiments (1), (3), (4), and (5) above, in which less than 100 per cent. of HCl is shown?" I reply there is no doubt that near the point at which the latter portions of HCl are being expelled, the temperature may easily attain such a pitch that ammonia also begins to be disengaged, the result being an apparent sublimation of ammonium chloride. Thus, some of the ammonia will also be missing as NH_4Cl , though this missing ammonia is chiefly retained by the excess of phosphoric acid, and obstinately resists the action of heat to expel it. Thus, I can well imagine in a large-scale application of this method, that whilst a large excess of phosphoric acid would be necessary for a full yield of HCl from the NH_4Cl , that excess would be continually encroached upon and diminished by the increased retention and "fixation" of ammonia, if I may so term it,—the very condition necessary for the first reaction, militating against the second.

ACTION OF WOOL ON AMMONIUM SALTS.

After the investigations of Champion (Comptes rend. 72, 330), and also of Bréinl and Knecht and Appleyard (this Journal, 1889, 457), with P. Richard (this Journal, 1888, 841), it is now generally admitted that the evidence has become very strong in favour of the view that wool behaves like an amido-carboxylic acid, or at all events like a substance containing as it were the latent elements of such an amido-acid. Champion has given this acid the name "Lanuginic acid," but it is no ordinary amido-acid, as Knecht shows, since it contains sulphur, like a proteid. Of course the existence in wool of the elements and also the latent elemental conditions of an amido-acid, was at first more or less hypothetical, but by adopting this hypothesis and then experimentally following it up, the investigators have found that it has been uniformly well responded to in the affirmative. To take a case as a popular illustration with dyers of wool with whom bichromate of potash or soda is largely used as a mordant for alizarin colours, there is no doubt that the chromic acid unites with some constituent of the wool to form an insoluble or slightly soluble chromate, whilst normal chromate remains in solution. Being thus fixed, and adopting the amido-acid hypothesis, we must consider it combined with the NH_2 or basic group in such amido-acid, which we might, for lack of further precise knowledge, represent as $(\text{X}) < \text{CO} \cdot \text{OH}$.

The interesting point, however, is, that the active groups in the alizarin colours are hydroxylic, and thus of acid character, and hence would require for fixation and combination the presence in the wool substance of some free basic functions or groups. But in our chromated wool we have just seen that the basic functions (NH_2), are already engaged and neutralised by the chromic acid radical. Hence such chromated wool ought, shall we say, theoretically, to be inert or unsuitable for the fixation of such hydroxylic-colours or acid colours as Alizarin blue, galleo, &c.

This is precisely the case, as the dyer finds it, and in order to shift the chromium into its proper place, viz., into union with the $\text{CO} \cdot \text{OH}$ or acid group in the amido acid, its function must be altered from that of an acidic to that of a basic substance, a polybasic substance indeed, so that besides union with the $\text{CO} \cdot \text{OH}$ group there shall be ample basicity to spare for the attraction of those hydroxy acid substances, the alizarin colours. The dyer, consequently, wanting the chromium in what he calls the "green state," i.e. as chromic hydrate, uses tartar (cream of tartar) along with the bichromate in mordanting. It is oxidised at the expense of the chromic acid on the fibre, which is reduced to chromic hydrate. The chromic hydrate still remaining united with the wool, as a basic group, we must of necessity now regard it as united with the $\text{CO} \cdot \text{OH}$ or acid group of the amido acid (wool), and united so as to form a kind of basic salt. Upon the wool therefore is now conferred prominently basic functions, there being the NH_2 group, vacated on the one hand, and the basic chromic group on the other, and this "green mordanted wool" is thus fully prepared to receive and fix acid or hydroxy compounds of the alizarin or similar types.

P. Richard (this Journal, 1888, 841) desiring further evidence of the presence of the amido group, and noting that wool behaves towards acid colours like a base and towards basic colours like an acid, tried to diazotise the amido group present in the wool. The wool was coloured straw-yellow by this treatment, and after treatment with alkaline solutions of phenols, such as resorcinol and α -naphthol, it assumed a red colour, and there appears no doubt that by the first action a peculiarly stable diazo-compound was obtained, which by the second, became united as would have been the case with an ordinary diazo-compound, with the phenol, forming a coloured compound.

Now remembering that though a basic substance of not very strongly pronounced alkalinity, yet aniline on heating with ammonium salts such as the sulphate is able to expel the ammonia, it occurred to me that possibly the amido group in wool, if united with any degree of similarity, although to form an insoluble compound (wool), might be able to expel ammonia from ammonium salts, on application of heat. Prof. J. J. Hummel of Leeds, kindly supplied

with some pure wool, and with this I experimented as follows, and with the following results. The wool was first washed by heating up to the boiling point with distilled water, wringing out and rinsing once more in cold water. It was then dried.

A.—1. 10 grms. of this wool were placed in a flask with 10 grms. of pure ammonium sulphate and about 100 c.c. of water, the vapours evolved on boiling the mixture being passed through sulphuric acid of known strength. After two hours' heating the excess of acid was estimated, and it was found that the H_2SO_4 had been neutralised to an extent equivalent to 0.0578 grm. of NH_3 .

2. In the same flask a mixture of the same volume of water and 10 grms. of $(\text{NH}_4)_2\text{SO}_4$ alone was now boiled for two hours, when it was found that the H_2SO_4 had been neutralised to the extent of 0.017 grm. of NH_3 .

3. In the same manner, 10 grms. of the wool alone were boiled with water only for two hours. Thus it was found that 0.0017 grm. of NH_3 was liberated by decomposition of the wool itself.

Hence the ammonia liberated by the agency of the wool is $(0.0578 - 0.017 + 0.0017 \text{ grm.}) \text{NH}_3 = 0.0391 \text{ grm.}$, or 1.52 per cent. of the total NH_3 .

B.—The previous experiments were now repeated, only that boiling was continued for four hours instead of two.

	Grm. NH_3
(1.) With 10 grms. of wool.....	0.0833
(2.) With 10 grms. ammonium sulphate alone.....	0.0272
(3.) With 10 grms. wool alone.....	0.0020
The wool therefore expelled $(0.0833 - 0.0272) \text{ grm.}$	
of NH_3	0.0561
Or 2.10 per cent. of the total NH_3 .	

C.—5 grms. of wool were next heated with 5 grms. of $(\text{NH}_4)_2\text{SO}_4$ and 100 c.c. of water, and in the same apparatus and under similar conditions as before; also 5 grms. of $(\text{NH}_4)_2\text{SO}_4$ with 100 c.c. of water alone.

	Grm. NH_3
After two hours' boiling, the wool with $(\text{NH}_4)_2\text{SO}_4$ gave.....	0.0289
Whilst the $(\text{NH}_4)_2\text{SO}_4$ alone gave.....	0.0102
And the wool alone.....	0.0010
The wool therefore expelled $(0.0289 - 0.0112) \text{ grm.}$	
of NH_3	0.0177
Or 1.37 per cent. of the total NH_3 .	

D.—10 grms. of wool were now heated with 5 grms. of $(\text{NH}_4)_2\text{SO}_4$ and 100 c.c. of water, and in same apparatus and under the same conditions as before, 5 grms. $(\text{NH}_4)_2\text{SO}_4$ with 100 c.c. of water.

	Grm. NH_3
After two hours' boiling, the wool with sulphate gave.....	0.0493
Whilst the salt alone gave.....	0.0102
10 grms. of wool alone giving.....	0.0020
The wool therefore expelled $(0.0493 - 0.0122) \text{ grm.}$	0.0371
Or 2.88 per cent. of the total NH_3 in salt.	

E.—10 grms. of wool were boiled for two hours with 2.5 grms. of $(\text{NH}_4)_2\text{SO}_4$ and 100 c.c. of water, 2.5 grms. of $(\text{NH}_4)_2\text{SO}_4$ alone being also boiled with 100 c.c. of water.

	Grm. NH_3
The wool with sulphate yielded.....	0.0401
The salt alone yielded.....	0.0078
The wool alone with water yielded.....	0.0017
The wool expelled therefore $(0.0401 - 0.0095) \text{ grm.}$	
NH_3	0.0306
Or 1.75 per cent. of the total NH_3 in salt.	

F.—20 grms. of wool, boiled for two hours with 1.5 grm. of $(\text{NH}_4)_2\text{SO}_4$ and 200 c.c. of water; also 1.5 grm. of $(\text{NH}_4)_2\text{SO}_4$ alone with 200 c.c. of water for two hours.

	Grm. NH_3
The wool (20 grms.) with sulphate gave.....	0.0425
The salt (1.5 grm.) alone with water gave.....	0.0040
Wool (20 grms.) alone with water gave.....	0.0033
The wool expelled therefore $(0.0425 - 0.0073) \text{ grm.}$	0.0352
Or 9.11 per cent. of the total NH_3 .	

G.—20 grms. of wool, boiled for six hours with 1.5 grm. of $(\text{NH}_4)_2\text{SO}_4$ and 200 c.c. of water; also 1.5 grm. of $(\text{NH}_4)_2\text{SO}_4$ and 200 c.c. of water; also 20 grms. of wool alone with 200 c.c. of water.

	Grm. NH_3
The wool (20 grms.) with sulphate gave.....	0.0630
The salt (1.5 grm.) alone with water gave.....	0.0078
Wool (20 grms.) alone with water gave.....	0.0075
The wool expelled therefore (0.0630 - 0.0153) grm.
Or 13.12 per cent. of the total NH_3 .	

Considering that we have here been making use of an insoluble, or almost insoluble, reagent to decompose the ammonium sulphate, I think on the whole the basicity of the amido group of the wool has given a very good account of itself, and has shown that it is decidedly capable of displacing ammonia in ammonium sulphate. I think, with regard to what follows the ammonia expulsion, that it is pretty certain we have a peculiar compound, or wool double salt, if I may so say, produced by the union of laniginic acid (wool amido acid) with bisulphate of ammonium, and it will be extremely interesting to ascertain next if this compound, which at the best is sure to be a rather unstable one, is to any extent soluble, in other words isolable.

Such a compound could be for the present formulated—

wherein (X) $< \text{NH}_2$
 CO.OH represents all that we know so far of the chemical constitutional structure of the wool compound, and in which (X) represents the remaining constituents of that compound. Knecht has already shown how firmly the elements of a basic alum unite with wool, when alum solutions are boiled therewith, free acid remaining in solution (this Journal, 1888, 622). Such an amido-acid structure further explains admirably why wool has such an attraction for dilute sulphuric acid, and at the same time is so readily attacked by the fixed alkaline hydrates, and is completely soluble in hot caustic alkalis. Knecht states that wool which had been boiled in water containing 10 per cent. of sulphuric acid (of the weight of the wool) had to be boiled nine times in succession for an hour at a time in fresh distilled water, before all the acid could be removed.

Though a feebly basic NH_2 group, yet doubtless, it is the presence of this group in the wool which accounts for the aforesaid attraction for sulphuric acid, and equally the presence of the CO.OH group accounts for the ready entrance of caustic alkalis and on heating of decomposition, and solution.

Finally, the structure represented, in conjunction with the fact I have succeeded in eliciting as to the decomposability of a salt like ammonium sulphate by wool, explain how much more safely ammoniacal liquids (ammonia soaps and ammonium carbonate solutions) may be used for the scouring and cleansing of wool and woollen fabrics, than fixed alkaline carbonates and hydrates. Nevertheless, in wool we have physical structure to consider as well as chemical structure, and this physical structure is injured by strong solutions even of ammonia on heating; very probably though unattacked at the point of the amido group, the wool substance is chemically vulnerable, to some extent, at that of the CO.OH group.

May I reiterate, in conclusion, that whilst speaking of wool as an amido acid, or behaving as one, it is very probable that, really, it would be more accurate to consider it as such a compound in a veiled state, somewhat as one would speak of glucose in a glucoside, for example. (See also E. Knecht, Fischer's Jahresber. der Chem. Tech. 1888, 1107.)

I have much pleasure in again acknowledging the able assistance of Mr. Albert Shonk in this investigation.

DISCUSSION.

Dr. R. MESSEL said that many years ago he made experiments on the point, but never found any apparatus in which he could carry out the reaction, so he gave it up. He used platinum at that time, and thought that possibly traces of fluorine were the cause of the platinum being attacked, but it was not so.

Dr. H. SCHLICHTER remarked that several points had struck him during the reading of the paper. Firstly, he did not believe that all wools behaved equally towards colouring matters. He remembered in one instance a mixture of two kinds of wool was dyed red, and it was found that the two kinds were very different under the microscope: one

was beautifully coloured, the other was not. As far as he remembered, Chevreul ascertained that the perspiration of different kinds of sheep was in many cases alkaline and in others acid, and this, taken in connection with the physical structure of the wool fibre, would explain the different behaviour towards the same colouring matter, and perhaps might be used to distinguish various kinds of wool under the microscope. Another very interesting point was as to the experiments which Knecht had made with sulphuric acid. He had always thought that wools treated by the carbonising process were not clean, but that some of the sulphuric acid remained in the fibre; and that would be a very important point in afterwards judging the quality of the wool and fabrics made from it.

Dr. S. RIDEAL said that when Mr. Watson Smith read the paper he used an expression new to him, namely, the "tenacity" of ammonia for phosphoric acid, instead of "affinity." He thought it a good word, which might be generally adopted with advantage.

The CHAIRMAN presumed that the author had made blank experiments with sulphuric acid and water, and that he had boiled the same quantity of sulphate of ammonia with water, with and without wool, to eliminate the error due to the amount of ammonia that might be given off on boiling the sulphate with water only. In a previous paper Mr. Watson Smith had strongly dwelt on the easy manner in which sulphate of ammonia suffered decomposition.

Liverpool Section.

UNIVERSITY COLLEGE, BROWNLOW STREET.

Chairman: G. Schack-Sommer.

Vice-Chairman: Eustace Carey.

Committee:

P. Bateson.
 W. D. Herman.
 C. L. Higgins.
 F. Hurter.

 A. Watt.

Hon. Treasurer: W. P. Thompson.

Hon. Local Secretary:

T. Lewis Bailey, University College, Liverpool.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—Chairman: Charles A. Kohn. Vice-Chairman: G. Schack-Sommer. Committee: J. Campbell Brown, Eustace Carey, M. Lloyd Davies, and W. Norris Jones.

SESSION 1895-96.

May 6th, 1896:—

Mr. W. J. Orsman. "Interaction of Carbonic Oxide and Coal Dust."

Dr. G. C. Clayton. "Chlorine as a Disinfectant."

Meeting held Wednesday, April 1st, 1896.

MR. EUSTACE CAREY IN THE CHAIR.

ON POISONING BY GAS: ITS PREVENTION AND CURE.

BY DOUGLAS HERMAN.

The frequent occurrence of fatal cases of "gassing" by sulphuretted hydrogen, producer-gases, carbonic acid, &c. is my excuse for making this brief communication.

At this date, no novelty can be claimed for the means I wish to bring to your notice, of, in the first place, preventing "gassing" altogether, or, when it has already taken place, of counteracting its results; but although there is nothing new in the principles involved, I think it plainly the duty of our Society, the members of which are responsible for producing such vast quantities of noxious gases, to make known as widely as possible the best means of preventing danger resulting therefrom.

When it is necessary to enter a flue, or other place where a dangerous atmosphere may be expected, it is a very simple matter to provide the workman with a supply of fresh

air. Of course this is done in some cases by a helmet, but the same result may be practically obtained, in the case of gases which do not too painfully affect the eyes, by means of a simple respirator covering the nose and mouth, and fed with a supply of air under pressure.

I have here an extemporised "muzzle," consisting of an ordinary india-rubber respirator, from which the sponge has been removed, and which has an air-supply tube substituted for the usual holes. I have known a man to work with this respirator for 20 minutes in a hot flue, full of producer-gas. The only inconvenience he suffered arose from the rather sharp edges of the rubber, and the escape of some excess of air in too close proximity to the eyes. To obviate these inconveniences I have devised another form. An india-rubber air cushion, as used with Brin's oxygen respirator, fits comfortably on the face; the air supply is brought in on one side and the excess, together with the expired air, escapes on the top. The air-supply tube is carried over the shoulder, and is secured to the jacket by a strong safety pin. The respirator can be put on in a second, being kept in place by a strong elastic band passing round the head. The whole thing costs about 5s., the most expensive item being the air cushion, which is sold at 3s. 9d., but could doubtless be supplied cheaper if ordered in quantity.

At the glass works we have a constant supply of air under pressure, but, where this convenience does not exist, the necessary air can readily be supplied by a foot blower, or even the ordinary domestic bellows, if of somewhat larger than usual size and combined with a reservoir of some kind to give constant pressure.

Now as to the treatment of persons who have been "gassed." What is wanted is obviously an immediate supply of fresh oxygen to the lungs, and this is most easily given by means of a cylinder of compressed oxygen. With this there is no difficulty in promoting artificial respiration, since, if a tube conveying a gentle stream from the oxygen cylinder is put in the patient's mouth and the lips held tightly round it, the oxygen, under pressure, forces its way into the lungs. It can also be supplied through one of the nostrils, the other being alternately closed and opened; or by a respirator covering the nose and mouth, but a plain tube in the mouth generally answers quite as well.

There do not appear to be any after ill effects—there is little or none of the distressing headache usual in cases of "gassing." So well is this understood, that men, who have had only a slight dose of gas, walk off, of their own accord, for a few whiffs from the oxygen bottle, as they say it prevents headache.

At my suggestion oxygen has now been kept on tap for some time at various works, and I am told several lives have been saved by its means.

I cannot too strongly urge all responsible for producing poisonous gases to issue plain instructions for the use of oxygen, and to always keep a cylinder in readiness for an emergency.

In addition to its use in the case of persons who have been poisoned by gas, compressed oxygen will be found of great service in the restoration of the apparently drowned, and I would suggest its being kept on hand at Royal Humane and British police stations, &c., as is now done in France.

I append instructions for the administration of oxygen.

Turn the tap on the cylinder till the oxygen flows out in a gentle stream through the tube; then, if the patient is *conscious*, place the glass tube in his mouth and let him draw the oxygen into his lungs until he feels relief.

If the patient is *unconscious*, place the tube, from which the oxygen is gently flowing, in his mouth, close the lips round the tube, and allow the oxygen to flow gently in a continuous stream into the mouth, alternately closing and opening the nostrils with finger and thumb in order to effect alternate inflation and deflation of the lungs. It is helpful to press the chest gently when opening the nostrils. Continue the operation until the patient can breathe the oxygen for himself.

The blowing out of the cheeks indicates when sufficient pressure has been introduced into the lungs. This pressure should not be too great.

A MODIFIED FORM OF SCHRÖTTER'S APPARATUS FOR THE DETERMINATION OF CARBONIC ANHYDRIDE.

BY CHARLES A. KOHS, PH.D., B.SC.

OF the many forms of apparatus for the estimation of carbonic anhydride by loss, that devised by Schrötter is probably most widely in use. Compared with other forms, it is certainly more handy than Bunsen's apparatus, although the latter is more accurate, since it contains an absorption tube charged with dehydrated copper sulphate on pumice in addition to calcium chloride. In a modified Bunsen apparatus described by A. Christomanos (Ber. 1894, 27, 2748), the drying tube is replaced by a small wash bottle containing concentrated sulphuric acid; the advantages of the latter over calcium chloride as a drying agent are pointed out. But this modified form suffers from the same disadvantage as the ordinary Schrötter apparatus in not making any special provision for the absorption of hydrochloric acid gas which is evolved whenever hydrochloric acid is employed in the decomposition of a carbonate. This is a well recognised source of error, and it is customary to attach a tube charged with dehydrated copper sulphate on pumice to the sulphuric acid bulb of the ordinary Schrötter apparatus in order to effect the complete absorption of the hydrochloric acid gas. With this addition, very reliable results can be obtained, but the method of attachment of the additional tube is always more or less clumsy. The object of the present modification is to overcome this, and the new form has two additional advantages. The apparatus is more stable, and the copper sulphate tube A can be easily turned

(Half actual size.)

through any angle at B, so as to attach the india-rubber tubing for drawing air through the apparatus, after heating to drive out the carbonic anhydride and allowing to cool. The pumice containing the dehydrated copper sulphate is held in place by a plug of glass wool, and the ground glass stopper C below it keeps well in its place if properly greased. If necessary it can be made perfectly secure by means of platinum wire. The total weight of the apparatus when fully charged is 58–60 grms.

Mr. J. Towers, of Widnes, has undertaken the supply of the apparatus.

THE WOOD CELLULOSE INDUSTRY OF SCANDINAVIA.

BY JAMES BEVERIDGE.

THE development of this industry within recent years has been so rapid, and its bearing on the paper industry of Europe is so great, that no apology need be made for introducing the subject to this Society. Both Norway and Sweden are by nature admirably equipped for this manufacture, as both contain vast forests of spruce or white pine wood; are intersected with magnificent water-ways, and are possessed of water-falls which in the aggregate represent great wealth. Indeed such a combination of cheap wood, the means of cheap transport, and the occurrence of mechanical force in the natural waterfalls has probably no parallel in any other country in the world.

By far the greater part of the timber grown in the forests of these countries consists of Scotch and spruce firs. A little poplar and birch occur in places, where a clearing has been made, but these represent a very small proportion of the wood of the country. The Scotch fir is not used for pulp making, the bulk of it, together with the larger spruce trees, being hewn down and sawn into boards, &c. in the numerous saw mills scattered over the country. The smaller spruce trees, those having an average diameter of from 7 to 8 ins., are the most suitable, and those grown in the vales, or on good soil, are preferable to those grown on the mountain tops. Especially is this the case in the north of Sweden, where the climate and soil exert an influence on what is known as vale wood in contra-distinction to mountain-timber.

Pulp wood is usually cut during the winter, when the tree is free from sap, and when the snow lies thick on the ground. The latter facilitates transport from the forest to the water-way. The hewn trees are freed from their branches, tops, and bark with the axe, and then drawn on sledges to the river side, or in many cases upon the ice covering the rivers or lakes. The labour of hewing, barking, and driving is all done by piece-work. When the spring time comes, and the snow on the hills begins to melt, and the ice in the rivers has disappeared, the logs are tipped into the rushing torrent and may travel many miles before they are finally collected again at the pulp factory. The logs are then taken from the river and piled in the factory yard to dry, a large stock being kept for winter use, as no floating can take place then.

To prepare the wood chips for the digesters, the logs are cut into lengths of about 2 ft., and carefully barked by machinery. Any black knots thus rendered visible are bored out, and the clean pieces of wood chopped into slices diagonally across the grain; these slices are then broken up, and the resulting wood chips are carefully freed from sawdust, and separated into two or three qualities by specially designed machinery. The well-known Bache-Wiig machine is in general use for this purpose. Of 100 parts of wood, thus treated, 80 per cent. rank as first quality, 15 per cent. as second, and 5 per cent. as third quality. Some manufacturers digest these various qualities separately, producing pulps of the grades named, while others are content to treat the chips as a whole, just as they are produced by the chopping machine.

There are in common use three processes for pulping the wood, namely, the soda, the sulphate and the bisulphite methods. Each of these yields a cellulose possessed of characteristic properties. Soda pulp is considered the softest of the three, bisulphite pulp the hardest, whilst sulphate pulp stands midway in this property, between the soda and the bisulphite. In each individual process, however, the conditions of boiling can be so modified as to yield almost any desired quality of pulp, and the above classification, according to the quality of softness, is very nearly so, of pulps consuming the same quantity, or very nearly so, of bleaching powder per unit weight of fibre bleached.

Soda Process.—The prepared wood in this method is digested for five or six hours at a pressure of 110 lbs. above atmosphere, in a caustic soda lye containing about 5.0 per cent. Na_2O , the total time required to complete one digestion being about 10 hours. This includes filling, digesting, blowing off, and emptying. The soda lye is separated from

the pulp by filtration, and the soda recovered in one of the many methods in vogue, whilst the pulp is washed, disintegrated, purified, and prepared for the market in the usual way.

Sulphate Method.—This is misnamed as the reagent in the digesting fluid, which performs the work of removing the incrusting matters surrounding the fibres, is not sulphate of soda, but substantially a mixture of caustic and sulphide. Salt cake is employed to yield the sulphide, and is added to the black carbonaceous mass in the calcining furnace during the soda recovery process. Sulphide of sodium is thus formed, and precautions are taken, not only in the construction of the furnaces, but in the mode of working them, especially with regard to the exclusion of air from the fusing mass, to facilitate its formation. The ash recovered in this process is causticised in the usual way before being used in the digester.

Some practical points are worth noting in this process. Firstly, there is a larger quantity of soda salts to be dealt with per unit weight of pulp produced than in the soda process pure and simple, due to the presence of much undecomposed sulphate of soda in the lyes; secondly, the presence of sulphide causes great wear and tear in the multiple evaporating apparatus, and it has in some cases been found cheaper to abandon the latter in favour of a brick furnace, constructed on economical lines; thirdly, the bad odour of the blow-off gases prevents its use in populous districts. In other respects the digesting of the wood and other operations are carried out as in the caustic soda process, with the exception that the pressure employed is usually a little higher, viz., 120 lbs. above atmosphere.

Bisulphite Process.—This is unquestionably the simplest and cheapest method for the preparation of paper pulp from wood. The digesting fluid is cheaper than soda, no recovery plant is necessary, and, the most potent factor of all, the percentage yield of cellulose per unit weight of wood is the highest. Bisulphites of lime, soda, and magnesia are in general use, the bulk of the cellulose being, however, manufactured with bisulphite of lime. Sometimes a mixture of lime and magnesia, or lime and soda, is preferred, the normal sulphites of magnesia and soda being soluble in water. The presence of soda or magnesia in the liquors is advantageous. It is assumed, and under certain conditions doubtless true, that when digesting with pure bisulphite of lime, some of the normal sulphite of lime in solution is precipitated upon the chips of wood during the early part of the process, and that the pulp ultimately produced is not so good as when the acid contains magnesia or soda, either altogether or in part. With regard to cheapness, the bisulphite of lime necessarily ranks first, because of the low cost of lime, either as caustic or carbonate, while soda takes the next place, provided it is prepared by the double decomposition of bisulphite of lime and sulphate of soda, thus—

There is not much difference between the cost of this and bisulphite of magnesia, excepting when the sulphate of calcium or pearl hardening ($\text{CaSO}_4 + 2\text{H}_2\text{O}$) obtained can be sold at its current market value, viz., 50s. per ton. The quantity of bisulphite of lime liquor required to yield one ton of air-dry sulphite wood cellulose can now be produced in this country for not more than 12s. 6d.

The sulphurous acid is obtained mainly from the combustion of brimstone or recovered sulphur. Although pyrites abound in both Norway and Sweden, and mining operations are continually being pushed forward on an extensive scale, yet this ore is not used in the cellulose industry. Some years ago a few manufacturers tried to use it, but for some reasons, difficult to understand, the process was abandoned. At a large works in the North of Sweden, which I have recently rebuilt, I had no difficulty in designing plant for the use of pyrites, and of obtaining high-class results in the boiling operation with the acid procured from this ore. The kilns were of the ordinary type employed in vitriol works in this country. Various kinds of sulphur ovens are in use, one of the most convenient being Ekman's, which consists of a wrought-iron box, the bottom of which forms the combustion hearth.

The absorption of the sulphur dioxide and production of bisulphite is carried out in a variety of ways. Some manufacturers employ high towers, square or circular, built of wood, a system first introduced by Mitscherlich in Germany and by Franke in Sweden. These towers are filled with limestone kept wet by a down-flow of water, and the water is regulated to yield at once an acid of the desired strength. Others, again, prefer a series of smaller towers, filled with limestone, through which the kiln gases pass in succession, the weaker acid from the back towers being pumped on to the front ones. In substance, this is the system advocated by the late Mr. Flodquist. In all cases an artificial draught is desirable, if not necessary.

Those manufacturers, however, who prefer using milk of lime, must have recourse to another method, in which the SO_2 gases are either forced or sucked through weak milk of lime, contained in a series of three or more tanks, arranged on different levels, so that the liquid in the second tank in the series can be run by gravitation into the first, and that from the third into the second, fresh milk of lime being placed in the third or last tank. The kiln gases are cooled before passing through these absorbers, and the milk of lime is kept in constant motion by suitable agitators. This method is employed by many German and a few Scandinavian pulp-makers.

Bisulphite of magnesia is made, according to Ekman, by passing the sulphurous acid gases through small towers, packed loosely with "slaked" magnesia, kept moist with water. The magnesia is obtained by calcining magnesite. Fry introduced the alternative method of passing milk of magnesia of the desired strength through a high tower of large area, packed loosely with an acid-resisting material, while the kiln gases were ascending.

Bisulphite of soda prepared by the reaction previously given, in a large tank fitted with an agitator, is separated from the sulphate of lime by filtration, the pearl hardening being dried, ground, and used as a loading in the manufacture of papers of a high class. The decomposition of the bisulphite of lime by the sulphate of soda amounts to as much as 95 per cent., when using weak solutions of bisulphite, and only a moderate excess of sulphate of soda. I have worked this process to the extent of several thousands of tons of pulp, with results which justify the belief that it certainly equals, if it is not superior to, any other.

The use of dolomite is almost entirely confined to the tank or vat system of bisulphite making, the mineral being previously burnt, "slaked," and ground to a paste with water. After dilution the MgO and CaO are saturated with SO_2 , and the absorption continued till the liquor has reached the required degree of richness in sulphurous acid.

All these methods of preparing the bisulphite liquors are in use in Scandinavia, and there seems no lack of enterprise in adopting any process, which offers a slight advantage over another.

The composition of the acid has an important bearing on the quality of the pulp. The relation of the sulphurous acid to "base" is closely watched, and in most cases regulated to a nicety. As a general rule, of 100 parts of total SO_2 present in the liquor, 34 parts, or practically one-third, are combined with "base," leaving 66 parts in the free state. The percentage composition of the acid varies with the system of boiling. If the pulp boilers are heated with steam injected into their contents, the acid is stronger than when the indirect system of heating with steam coil or jacket is used; in the former case the acid contains as much as 5 per cent. of total SO_2 , of which 34 per cent. are combined with "base"; in the latter case a 4 per cent. acid at most is considered strong enough. But the strength of acid and the regulation of many other conditions depends entirely upon the quality or kind of pulp which one desires to produce.

The modifications in the wood boiling operations are almost as numerous as those pertaining to the preparation of the bisulphite or soda lyes. I have briefly touched upon this particular when speaking of the soda and sulphate processes. It is only necessary to add that in these two processes the wood digesters used are single shelled, usually upright stationary cylinders of great strength, equipped with the simplest fittings possible. They are invariably

heated with injected steam, and no vomiting arrangement for circulating the soda lye, such as is used in esparto boilers, is required. After the maximum pressure is reached it is maintained for a few hours, and then the pressure is blown off. The time given, at above 100 lb. pressure, is usually about 5 hours. The blow-off steam is utilised in doing useful heating and evaporative work.

The sulphite pulp digesters, on the other hand, are much more elaborate pieces of apparatus; they are of two types, viz., rotary and stationary. The shells of both are of the usual steel plates, and double riveted with butt joints. Owing to the corrosive action of the bisulphite liquor they must be lined internally with sheet lead, or some other acid-resisting substance, and among the latter quite a number of different sorts of linings are in use. Mitscherlich was the first to suggest, and, in fact, to use a lining of cement and bricks, and since then much ingenuity has been displayed in the combination of the materials composing the linings, and the mode of laying these materials upon the interior walls of the digester. Nearly all employ flat tiles, with Portland cement, made into a thick paste with silicate of soda and water, as mortar. Mitscherlich recommends a brick 4 ins. thick, whose sides are tongued or grooved; others prefer a thin tile 2 ins. thick by 9 ins. by 6 ins., rough on one of the flat sides and the four edges, and curved or shaped in accordance with the position they occupy inside the digester. These tiles are fixed in a double layer in such a manner that the joints of the one will cross those of the other. The whole interior surface of the boiler and neck pieces is thus covered, and when this type of lining is carefully executed it effectually prevents the acid from attacking the iron plates.

Very much could be said on the different methods of lining sulphite digesters, but the principle and practice of Mitscherlich has stood the test of time, and has been largely imitated, and, indeed, his original plans improved upon.

The fittings (by which is meant all cocks and valves fixed to these digesters) are of the best gun-metal, but in Scandinavia, as elsewhere, there has been introduced another alloy which is cheaper, and answers equally as well as any alloy of copper and tin.

In rotary boilers, whether spherical or cylindrical, the acid and wood are heated with steam injected through the trunnion ends, the injection pipe being of gun-metal; in stationary digesters the usual practice is to heat with two or more steam coils of hard lead piping placed inside. In the latter case the heating is under more perfect control than in the former, and as the process of digesting is a delicate operation the indirect system of heating is obviously preferable. As the indirect method was the first introduced the older works in Norway and Sweden still employ it.

The digesters vary considerably in size, some of the smallest yielding but 17 or 18 cwt. of dry pulp per charge, whilst of the modern boilers the largest yield from six to seven tons. Some manufacturers boil the wood slowly, as in the Mitscherlich system, whilst others prefer quick boiling. In the Mitscherlich system about 250 to 300 cub. ft. of digester capacity are required per ton of pulp per week, but in Scandinavia few, if any, employ so much. Some use from 100 to 120 cub. ft., others from 55 to 65 cub. ft. The prevailing circumstances control the duration of the digesting process to a great extent; but there is no doubt large boiler capacity, careful judicious heating, and the proper proportioning of the acid to the wood, all tend to enhance the value of the final product. The actual number of hours occupied in the digesting process is about 50 in the Mitscherlich system, in others 24, while 9 or 10 hours are all that are given in the quickest method.

The pulp, after it is removed from the digester, is separated from the waste liquor in drainers, then washed with water, broken up, purified, or freed from knots, &c., and finally felted into a thick web of dry paper on a paper machine, and cut into sheets before being packed in bales for the market. In the most modern works the apparatus used for each of these operations is of the most efficient, yet simplest, description.

The waste sulphite lyes from the wood digesters are usually run away into the rivers as useless, and as the question of river pollution has not assumed the prominence

in Scandinavia that it has in Germany, England, and other countries, this way of disposing of them can be followed with impunity. These lyes contain a few products, which in most cases can be recovered with advantage. They contain small quantities of sulphurous acid and sulphite of lime, both of which are partly recovered in many works by precipitation with lime, but the organic compounds are neglected. Mitscherlich has perfected a process for making a dextrine and other useful products from these lyes. The process is being applied in German and Austrian works. These products are sold in a syrupy condition with about 60 or 70 per cent. water, but as the quantity obtained in the manufacture of 1 ton of cellulose amounts to from 2½ to 3 tons, if sulphite makers were universally adopting this method of utilising the lyes, the market would soon be vastly over-stocked. The attention of technical chemists has been concentrated on this subject for many years, but so far they have been baffled in their efforts to extract, from the lyes, products, which would possess a value exceeding their cost of production, and at the same time, command a ready sale. The various systems of recovering the gaseous SO_2 mixed with the steam when blowing off the digesters, have been largely adopted. In principle, these consist in first cooling the gases in coils immersed in cold water, and allowing the SO_2 to pass to the limestone towers or milk of lime absorbers. Sometimes the gases are blown into cold bisulphite liquor.

Where the recovery of the sulphur (as SO_2) is carried out with care and skill, the sulphur consumed is about 10 or 11 per cent. on the air dry pulp produced. Such an excellently low result is seldom, however, obtained, the usual consumption being from 14 to 16 per cent.

Generally speaking, the modern mills of Scandinavia are well arranged. Water power being plentiful, the sites are selected to yield it cheaply by means of turbines. Very few mills are driven by steam. The power required to drive the machinery is small; 3½ horse-power actual being sufficient per ton of cellulose per week in mills producing 5,000 tons or so a year. For smaller works it is a little greater. This includes everything—acid department, wood cleaning and chopping, breakers, strainers, and all miscellaneous pumps and machinery. The fuel consumed, which in many cases is wood, depends entirely on the internal arrangements of the factory, but where coal is used for the boiling and drying and water for the motive force, 21 cwt. to the ton dry cellulose is ample, whilst 30 to 32 cwt. is sufficient in steam-driven mills.

The immediate future of this industry does not appear bright, due to over-production and the consequent fall in values. Notwithstanding this, many new factories are being projected or being established, which, by their natural position, &c., offer some advantages over the older works. Cheap wood and facilities for direct shipment are essential to the success of any modern factory. The cost of production seems to have reached its lowest limit in many districts, particularly in those showing a scarcity in the pulp-wood supply. Indeed, "the survival of the fittest" is imminent in many cases. Both Norway and Sweden have, however, vast resources with regard to this and the paper-making industry, and, as the older works die out, new ones are sure to spring up elsewhere, equipped with the most modern methods and machinery.

ON A METHOD OF CALCULATING THE AMOUNT OF STEAM REQUIRED TO DRY A TON OF PAPER OR PULP.

BY JAMES BEVERIDGE.

On the 7th of February 1894, while reading a paper before this Section of our Society on "The Manufacture of Straw Cellulose," I mentioned, under the division of "Fuel" (this Journal, 1894, 106), the principles upon which I founded a method of ascertaining, by calculation, the amount of steam (or coal) required to carry on the different operations in the manufacture of straw pulp. It will be remembered, the total fuel required to produce a ton of pulp was divided into three parts, viz., the quantity required, 1st, to boil the raw fibrous stock; 2nd, to disintegrate the fibres, &c.; and 3rd, to dry the pulp obtained on the drying machine. I now propose to touch upon the third of these divisions, and

to give in detail the formula I have used in ascertaining, by calculation, the steam required to dry paper or pulp on the Fourdrinier paper machine.

The apparatus for drying the web of paper or pulp, formed on the Fourdrinier wire, is so well known that a detailed description of it is unnecessary. Briefly stated, it consists of a series of three pairs of press rolls and then a set of polished cast-iron cylinders, of somewhat large diameter, heated internally with steam. The wet web of paper passes first of all through the press rolls, which press out the bulk of the water, and finally over the drying cylinders. These cylinders are arranged parallel to one another, and are driven by means of toothed wheels geared together. The condensed water accumulating inside of them is lifted by "buckets" fixed on the inside of the end covers, and discharged automatically through the back trunnions, while the supply of steam is admitted through the other or front trunnions, and can be regulated by taps attached thereto. When paper is being dried, the wet web is pressed tightly against the polished surface of the drying cylinders with the aid of endless belts of thick woollen or cotton felts, which travel along with it in the same direction and with the same speed. These felts are to prevent the paper from "cockling." In pulp works, however, where this system of drying is employed, felts are not used, excepting in the case of the first drying cylinder; even this arrangement is a matter of convenience rather than of necessity, the web of pulp being sufficiently thick and strong to be run taut around the drying cylinders without fear of breaking.

From this brief explanation the conditions under which the web of paper or pulp is dried will be easily understood. It is cold as it passes to the first of the drying cylinders, and is gradually raised in temperature as it travels over the others, till it reaches 212° F., when the water it contains is converted into vapour. The temperature of this vapour cannot very well be under 212° F., because the steam pressure within the cylinder is usually maintained at from 8 lb. to 10 lb. pressure above atmosphere, which will correspond to a temperature of from 236° to 240° F., and in the case of paper, the felts press the wet web against the hot iron surfaces. The wet paper thus held against the hot cylinder must nearly approach the temperature of the iron, although, for obvious reasons, it cannot exceed the boiling point of water under atmospheric pressure, excepting at the end of the range, where the web is dry. In the best paper-mill practice it is usual to avoid overheating of the cylinders with steam, to prevent too rapid drying.

The actual work done by the steam within the cylinders is obviously, first, to raise the temperature of the wet web to 212° F., and then to convert the water in the web into steam at 212° F. If, therefore, we know the initial temperature and weight of the water thus evaporated per 1 cwt. of dry paper made, the units of heat absorbed in doing this evaporation can be ascertained on well-established lines. So also, if the pressure of steam maintained within the cylinders be known, it will be easy to ascertain the amount of steam condensed in order to supply the above units of heat. If the former quantity be divided by the latter, we get the steam required to convert into steam at 212° F. that amount of water associated with 1 cwt. of dry paper in the wet web. This can be expressed in the following formula:—

$$S = \frac{x(T - t)}{T' - t} \dots\dots\dots (a)$$

in which—

S = lbs. of steam required,

x = lbs. of water to be evaporated per unit weight of dry paper made.

t = the initial temperature of the pulp or wet paper passing on to the drying cylinders.

t' = the temperature of the condensed water within the drying cylinders (*i.e.*, temperature corresponding to the steam pressure).

T = the total heat units in 1 lb. of steam at the boiling point of water under ordinary atmospheric pressure.

T' = the total heat units in 1 lb. of steam at the pressure prevailing within the drying cylinders.

The following example, based on the conditions prevailing in the trial from actual manufacturing practice given further on, will serve to illustrate the general application of the formula. Assuming $x = 261.2$ lb.; $t = 60^\circ$ F.; $t' = 236^\circ$ F.; $T = 1.179$; and $T' = 1.186$. Putting these values in their places in the formula, we have—

$$S = \frac{261.2 (1.179 - 60)}{1.186 - 236} = \frac{292282.8}{950} = 307.4$$

or 307.4 lb. of steam were required to evaporate the water associated with 1 cwt. of dry paper in the wet web.

It is obvious that during the drying, the paper itself has been raised from its initial temperature, t , to the final temperature, t' , and that the heat thus absorbed must also be calculated and added to the foregoing amount. I find the heat thus absorbed and the steam required to yield it under the conditions prevailing in this case by the well-known formula for all such instances in which simple heating is concerned, viz.:—

$$S = \frac{w s (t' - t)}{T' - t} \dots \dots (b)$$

in which w = the weight of dry paper, s its specific heat, while T' , t' and t have the same values assigned to them above given. The specific heat (s in the formula) of paper or cellulose I usually take as 0.55, which I believe near enough to cover all cases in which the composition of the paper does not vary greatly. Taking w as being equal to 112 lb., by substitution we get—

$$s = \frac{112 \times 0.55 (236 - 60)}{1.186 - 236} = \frac{10842.2}{950} = 11.41 \text{ lb.}$$

of steam for every cwt. of paper dried. The sum of this and the previous quantity, namely $11.41 + 307.4 = 318.81$ lb., represents the total theoretical amount of steam taken to dry 1 cwt. of paper or pulp. It is apparent that formulae (a) and (b) may be combined thus:—

$$S = x (T - t) + w s (t' - t) / T' - t$$

How far these quantities correspond to the amount of condensed water flowing from the drying cylinders of a Fourdrinier machine, upon which a white printing paper of good quality was being dried at a speed of 176 ft. per minute, will be seen from the following actual measurements:—

Total paper dried per hour = 1,100 lb.

Total water evaporated per hour = 2,566 lb. = 261.2 lb. per cwt. paper.

Temperature of wet web, $t = 60^\circ$ F.

Pressure of steam in drying cylinders = 8 lb. above atmosphere = 236° F.

Total water condensed within the cylinders = 3,710 lb. per hour taken by measurement as @ 62° F.

The actual steam used in this trial per cwt. of dry paper made on the reel was 377.74 lb., the difference between this and the sum of the two amounts found by the formulae being 58.9 lb. This difference, amounting to 18.6 per cent. on that found by calculation, is due to several causes, notably, moisture in the steam, and loss of heat by radiation.

The presence of moisture in the steam is inevitable, unless superheating is in use, and will exist to a greater or less extent in accordance with the arrangement and quality of the steam plant. In well-arranged works it seldom exceeds 3 per cent. of the weight of water evaporated in the steam boilers, and an allowance for this should be made to this extent in the above calculations.

After making this allowance in the foregoing figures, there is left a quantity equal to 15 per cent. nearly of the whole steam used, which is due to loss of heat by radiation, &c. It was to ascertain this loss that these formulae were originally constructed. I have found it to vary enormously in different mills, but the factors which control it are somewhat easily traced. In mills where the work of drying is constantly kept going, such as "news" mills, the machines in which are run on the same class and quality of paper during the whole week, with quick speeds and few changes and stoppages, it is reduced to a minimum, especially if the drying cylinder ends are cased in with hollow sheet-iron

covers, and the steam mains are well protected with non-conducting cement. According to my experience, this loss also varies with the quantity of paper dried. Obviously it will also vary inversely with the width of the machine, for in wide machines the free radiating surface is comparatively less to the weight of paper dried than on narrow machines.

In those mills where the steam used for drying is taken direct from the steam main, it is reduced from a high to a lower pressure by means of a reducing valve before it enters the drying cylinders. But in very many paper mills the drying is accomplished with the exhaust steam from the engine driving the paper machine. In both of these cases the steam entering the paper machine cylinders is wet, due of course to the reduction of its pressure, and any condensation occurring in the connecting pipes, between the reducing valve and drying cylinders, can be caught and measured, and if thought desirable due allowance made for it in the calculations, to arrive at a closer estimate of the loss by radiation. It has been usual for me to allow 1 per cent. of the quantities found by the formulae for every 10 lb. the steam pressure has been reduced.

The above trial closely agrees with the quantities found by calculation. It would appear that a 10 per cent. loss of steam due to radiation alone is inevitable, as the machinery in this particular case was in first-class order and every precaution taken to prevent loss of heat. It also closely agrees with the figure of 3 to 3½ lb. of steam given by Hoffmann as being required to dry one ton of paper.

SESSION 1895-96.

May 8th.—Discussion of all papers read during the Session already in print.

Meeting held Friday, April 10th, 1896.

MR. GEORGE E. DAVIS IN THE CHAIR.

DESCRIPTION OF A SIMPLE FEED-WATER HEATER.

BY PETER HART, F.I.C.

MANY small leakages of material occur in works which when looked into are found to be of greater amount than they seemed to be at the first casual glance. Exhaust steam is one of these, which might frequently be made use of for some purpose if not reconveyed into the boiler.

Like all other sulphuric acid works, the one with which I am connected uses compressed air largely for the purpose of forcing acid from the eggs to the top of the Gay-Lussac and Glover towers. The work of the two air pumps employed, working sometimes singly and sometimes together, may be taken as at least equal to one being kept constantly at work during the whole 24 hours. It occurred to me some time ago that, as these pumps are situated immediately adjacent to the boilers, it would be no difficult matter to return this steam to the boilers which supply steam not only to these engines but to the rest of the works. I have

heard of this steam being injected into the vitriol chambers but this method does not commend itself to me—holding as I do the opinion that all the input of a vitriol chamber, whether it be steam, sulphurous gas, or nitrous gas, should have a constant relative proportion to each other so far as possible during every fraction of the time they are working, and that irregular additions of any one of the constituents are calculated to disturb their working.

Of course there remained the choice of a great number of makes of apparatus for this purpose, but many of them

were not constructed on sound scientific principles, and, further, were very expensive. It occurred to me that one might be constructed combining the action of the well-known condensing or hydrochloric acid tower together with Siemens' regenerator, treating the steam as a gas soluble in water, which it is, using surface-furnishing material of a nature to absorb heat. Eventually the idea settled down into the shape shown in the drawing. A is a portion of an old boiler flue, 3 ft. diameter and 10 ft. high, the lower end of which has been securely

closed. About 18 in. from the bottom rests a cast-iron grid, with wide slits supported on projections attached to the interior of the cylinder, but which are not shown in the drawing; the upper space above this, to within a short distance of the top, is filled with boulder stones such as are commonly found in brick-clay or may be seen on most Lancashire shores. These should be selected as round as possible and of such size that the mass if so shaped would form a sphere of about 2 or 3 ins. diameter. Above this is seated a portion of a liquor cask of such a size that it will project some 6 or 8 in. into the iron cylinder and yet allow a ring of unfilled space of about 1 in. all round; this is kept in position by means of several wooden wedges attached to the cask. This cask has its bottom perforated with numerous $\frac{1}{2}$ -in. holes, and inside it is mounted the well-known oscillating box, commonly known as the "tumbling box" or "tumbling tub." The drawing now explains itself: the water, being turned on into the oscillator, is thrown over the bottom of the cask, through the holes in which it is distributed over the mass of stone packing, finally reaching the space below the grid; but during its passage down it has met the ascending hot exhaust steam, which enters at B, and having become heated by means of this, runs out at C into the cistern D, and thence, taken in hand by the pump E, is finally forced into the boiler. The advantage of the boulder-stone packing is that it absorbs a large quantity of heat, and if the pumps should be stopped for a time the water still runs out hot, taking its heat from that stored up in the packing; it acts thus as a regulator. The temperature of the water in the cisterns averages 160° F., and as about 7,000 gallons per day are put through it, this means a considerable saving. In our case I calculate it into nearly 3 tons of coal per week—not a large sum, but still a good

return for such a small outlay. I need scarcely say that water of 160° F. cannot be easily injected into the boiler, and that a pump must be used, and this in its turn must be placed, as shown, at a lower level than the cistern, in order that the water may flow into the pump by gravity. I cannot say that the dimensions given are the best; they were arrived at more by intuition than practice. In fact, the apparatus has turned out too small, for though it will deal effectually with the exhaust steam from one pump, if two are working its limit of efficiency is soon reached, and steam escapes at the top; this of course only means more cubic content of packing, to be attained by a taller or wider tower.

THE FUNCTIONS OF ALBUMIN AS A FIXING AGENT FOR PIGMENTS ON COTTON.

BY R. J. FLINTOFF, F.C.S., ETC.

The present communication is a result of experiments made to determine the properties of some insoluble azo-colours printed on cotton as pigments, and therefore a few words with reference to these experiments are necessary.

Many beautiful and fast shades are produced on cotton by passing cloth prepared with a solution of β -naphthol through aqueous solutions of some diazo-compounds. It seemed desirable to prepare some of these insoluble oxy-azo bodies, to print them on cotton in conjunction with albumen, and note the characteristics of the colours so produced.

The pigments were prepared by precipitation from aqueous solutions by mixing solutions of sodium β -naphthol and a diazo-compound.

The following table gives the necessary data respecting the nature of the pigments prepared and the colours they produced on cotton-cloth:—

Colour of Pigment.	Constitution.	Prepared from		Shade produced by Printing on Cotton in conjunction with Albumin.
		Naphthol.	Diazo-Compound of	
1. Brilliant Red.....	$\text{C}_6\text{H}_4\text{N}_2\text{NO}_2\text{C}_6\text{H}_4\text{OH}$	Beta.....	Para-nitraniline.....	Orange.
2. Ruby.....	$\text{C}_6\text{H}_4\text{N}_2\text{C}_6\text{H}_4\text{OH}$	Beta.....	Alpha-naphthylamine.....	Heliotrope.
3. Dark Chocolate.....	$\text{C}_6\text{H}_4\text{N}_2\text{C}_6\text{H}_4\text{OH}$	Beta.....	Benzidine.....	Drab.

It was found necessary to precipitate these compounds from very dilute solutions, otherwise the precipitates formed were in a state of such fine division that filtration was impossible. After allowing the precipitates to drain on a cloth filter for a week they contained about 50 per cent. moisture, and by exposure to a temperature of 100°C . could be dried completely and ground to a fine powder.

By the addition of oleine to the solution of sodium- β -naphthate and of acetate of sodium to the diazo-solution, somewhat brighter shades were produced, but in this case the precipitate dried to a horny, adhesive mass.

I do not think these pigments will be of much interest to the calico printer; they may, however, find some application in certain resist or discharge styles, notably in the case of aniline black. Two printing pastes containing the same percentage of colouring matter, only to the one an addition of a solution of albumin was made, were printed on the same fent with the same roller at the same time and dried. At once the colour containing the albumin appeared to be the more intense of the two, and after ageing through the Mather and Platt machine the phenomenon was even more pronounced.

I have only been able to find one explanation respecting the part played by albumin in the fixing of pigments, which states the property of albumin to be one of "occlusion."

I understand this to mean that the albumin, when coagulated, surrounds the small particles of pigment and fibre, binding them together.

Now there can be no doubt that this property is entirely inadequate to give a rational explanation of the effect above described.

From the data so far collected, one would probably conclude that the oxy-azo pigment and the albumen had chemically combined and formed a compound of greater colouring power than the pigment alone. Yet this is the more surprising when it is remembered that the pigment exists in the printing colour in a state of suspension and not solution, and, therefore, for chemical union to take place with such relatively large masses would justify the assumption that a strong affinity exists between these bodies.

Generally in the production of colour lakes on the fibre the compounds necessary for their formation are mixed in a soluble form in some suitable medium and then rendered insoluble by combination being effected in some after process. This method of procedure insures evenness of shade and facilitates the more complete combination of the component parts of the coloured body.

In fact, in many cases it would be a total impossibility to obtain a colour lake on the fibre possessing the required qualities without first rendering the colouring matter soluble in some suitable medium. Yet in the above case the particles of pigment are in very much larger masses and aggregates, and therefore the combination of two inert substances under such conditions appears very remarkable. Again, these colours possess a rather doubtful salt, forming group hydroxyl.

It has been pointed out that the sulpho-group is a lake-producer in conjunction with albumen, yet we know that the isolated hydroxyl group has only feeble lake-forming properties, and therefore its combination with albumen would be the more unexpected.

Experiments were now devised to ascertain the truth of this theory, and for the purpose a yellow pigment (lead chromate) was considered suitable, because, being a normal salt, lake formation would be impossible. Yet here we had the same phenomenon. The fibre on analysis gave traces of lead sulphide, which had evidently resulted from the presence of sulphur in the albumen, and therefore this

might possibly account for the darker shade. On account of this objectionable property of any lead salt, it seemed desirable to repeat the experiment with pigments produced by a combination of any adjectival colouring matter containing the orthodihydroxy group and the oxides of the metals chromium, aluminium, and calcium, whereby any possibility of black sulphur compounds being produced would be entirely eliminated. Again the result was the same, and consequently the theory of lake formation had to be abandoned, and the explanation sought for on other grounds.

If we take some cloth on which has been printed two mixtures, one containing a pigment alone and the other a pigment *plus* albumen, the proportion of pigment in each case being the same, and the same quantity of each mixture being on the fibre, then, on holding the cloth to the light, and viewing the light through the cloth, we shall find that in one case much more light is transmitted than in the other, and on examination it is found that the one containing the albumen is the more opaque. Therefore in this case more light should be reflected and we should have a darker colour.

Again, by examination under the microscope it is found that the albumin pigment presents a far more even and solid surface; this also will tend to increase its reflecting properties. But in the other case the small particles of pigment are readily seen sticking to the fibre, and the general effect is entirely lacking in the solid and smooth appearance characterising the former. The phenomenon, then, is purely an optical one, and depends upon the fact that in one case the actual quantity of light rays reflected is greater than the other.

Finally, I say the functions of albumin are twofold, viz., the well-known one of "occlusion," and the other of being able to increase the opacity of the layer of colour, at the same time to increase its reflecting power and thereby to apparently increase the colour of the body. This function I have named "intensification." The property of intensification is not confined to albumin, but is possessed by many substances capable of holding pigments in a homogeneous state in suspension and also of forming a suitable medium for their even distribution over the surface of the cotton fabric.

ON THE PREPARATION OF WATER FREE FROM AMMONIA.

BY JOSEPH BARNES, F.I.C.

THE preparation of water free from ammonia, either by fractional distillation or by the process of long boiling with carbonate of soda, as recommended by the "Water Committee" of the Society of Public Analysts, is always a somewhat tedious operation. The well-known destructive action of the halogens chlorine and bromine on ammonia does not appear to have been made use of for ridding distilled water of this impurity. These agents, however, afford us a means of preparing water absolutely free from ammonia in a very simple and expeditious manner. If a small quantity of bromine is added to ordinary distilled water and the latter boiled for a few minutes, all traces of ammonia will be destroyed. The same result is obtained by allowing the action to go on for several hours in the cold. Much more rapid, however, is the action of an alkaline hypobromite, which will destroy every trace of ammonia in the space of a few minutes in the cold. Water which has been treated either with bromine or a hypobromite cannot be used for Nesslerising purposes until all remaining traces of these reagents have been removed or destroyed, otherwise

there will be a destruction of ammonia in the standard solution used for comparison; potassium iodide effectually serves this purpose, and the method resolves itself into the following simple operations:—

One or two litres of ordinary distilled water are placed in a stoppered bottle and a little bromine vapour is then poured into it. After shaking, the water should be just perceptibly tinted, and should give a blue coloration when dropped on iodide and starch paper. One drop of a strong solution of caustic soda is now added and the bottle again shaken and placed on one side for ten minutes. Finally, one or two drops of a solution of potassium iodide are added, and the water will then be found to be free from ammonia and suitable for Nesslerising purposes.

Meeting held in Glasgow on Tuesday, April 7th, 1896.

DR. JOHN CLARK IN THE CHAIR.

ESTIMATION OF ANTIMONY IN ORES AND METALS, &c.

BY JOHN CLARK, F.I.C.

There is probably no mineral the valuation of which is in such an unsatisfactory condition as that of antimony ore. To a large extent this is the fault of the consumer or smelter, who insists on the antimony being estimated by dry assay, which usually means fusion with soda carbon and iron. Carnot has pointed out (*Annales de Mines* 1892, Vol. 1, p. 303) that this method is very inaccurate, the results being rarely within 8 or 9 per cent. of the truth; and after many experiments he has abandoned dry methods on account of the volatility of the antimony. I can confirm what Carnot says as to the inaccuracy of estimating antimony by dry assay, but in my experiments I found that the loss of antimony was frequently more than counterbalanced by the sulphur and iron which the antimony contained.

Thus, an ore which gave by wet assay 46.80 per cent. of antimony, yielded by dry assay 49.0 per cent., and a well-known analyst found 52 per cent. by dry assay in a duplicate sample. To get rid of the difficulties connected with dry assay, Carnot dissolves from 2 to 5 grms. of the ore in HCl, precipitates with tin, and collects the antimony on a weighed filter, by which means he says he obtains a result within 1 per cent. of the truth. He admits, however, that when the ore contains lead, that metal is partly precipitated on the tin, and this he says may be estimated by treating the weighed metal with polysulphide of sodium, which dissolves the antimony and leaves the lead as PbS. When arsenic is present it is also precipitated with the antimony, but, according to Carnot, no method of estimating the quantity has been devised.

The difficulty of the arsenic can easily be overcome by dissolving the ore in a mixture of HCl and FeCl₃, and distilling off the arsenic, as I have shown on a former occasion (*this Journal*, 1891, 444), and if the antimony is precipitated with iron instead of tin, none of the lead comes down with the antimony; but the metal obtained in this way, especially when working with 5 grms. of ore, is apt to contain impurities derived from the iron, and to oxidise to a considerable extent in the process of drying, but it can be purified and obtained in the compact condition by fusing the precipitate with cream of tartar and borax. It is necessary, however, to stamp the flux into the bottom of the crucible and place the precipitate in a small opening in the centre, as otherwise the loss of antimony is very great. The ore above referred to, when treated in this way, gave 44.8 per cent. of antimony, the difference being due to volatilisation.

when it is mixed with Rochelle salt rendered alkaline and titrated with $\frac{N}{10}$ iodine in presence of a considerable excess of bicarbonate of soda.

The following results were obtained in this way:—

(a.) Antimony prepared from tartar emetic:—

Antimony taken.	Antimony found.	Antimony per Cent.
Grm.	Grm.	
0.2	0.1998	99.90
0.2	0.1998	99.90

(b.) White metal giving 7.38 per cent. of antimony by another process:—

White Metal taken.	Antimony found.	Antimony per Cent.
Grm.	Grm.	
0.5	0.0372	7.44
0.5	0.0372	7.44

(c.) Alloy containing about 80 per cent. of lead:—

Alloy taken.	Antimony found.	Antimony per Cent.
Grm.	Grm.	
0.5	0.0686	13.92
0.5	0.0689	13.98

In presence of copper the antimony by this process comes out low. This seems to be due to the cuprous salt and its tendency to oxidise and become a carrier of oxygen to the antimony, as I observed in my experiments with mixtures of copper and antimony that when the last traces of free iodine were removed with sulphite of sodium the blue colour reappeared after a few seconds, indicating a fresh liberation of iodine, which does not take place when copper is absent. When copper is present it is therefore necessary to remove the copper before titrating antimony with iodine, and this can be most readily effected by converting the metals into sulphides and dissolving out the sulphide of antimony with caustic potash or caustic soda.

Separation of Antimony and Arsenic.—Antimony can also be estimated in mixed sulphides of arsenic, antimony, and tin by dissolving the sulphides in HCl and iodine, but in this case it is necessary to distil off the arsenic by boiling down repeatedly with a considerable volume of strong HCl to about one third of the bulk. The residual liquid which contains the antimony and tin when present is then filtered to remove separated sulphur and titrated with $\frac{N}{10}$ iodine after conversion into alkaline tartrate.

Known quantities of tartar emetic and arsenious acid converted into sulphides and dissolved in HCl and iodine gave the following results after boiling down three times with 50 c.c. strong HCl:—

Tartar Emetic taken.	Arsenious Acid taken.	Iodine used.	Tartar Emetic found.	Tartar Emetic.
Grm.	Grm.	C.c.		Per Cent.
0.5	None.	30.7	..	100.00
titrated direct.				
0.2	0.14	12.3	0.2063	100.15
0.1	0.07	6.1	0.09964	99.64

The arsenic which is volatilised can be distilled into water, but it cannot be titrated direct as it contains more or less iodine, and when diluted sufficiently with water to prevent volatilisation and boiled to get rid of iodine, the arsenic is partially oxidised to arsenic acid, and therefore not suitable for titration with iodine in an alkaline solution without reduction.

THE SULPHURIC ACID PROCESS OF REFINING LIXIVIATION SULPHIDES.

BY FREDERIC P. DEWEY.

THE time is fast approaching when more chemistry must be used in the extraction of the precious metals in the United States. The chief objections to chemical methods are the technical skill required in the management, the higher grade of labour necessary, and the time required to turn out product, thus locking up large amounts of capital; but these difficulties are becoming less applicable all the time. Then, too, the wonderful success attained in this country in extracting the precious metals by smelting the lead has retarded the application of chemical methods.

The chemical process of extracting silver by lixiviating or leaching its ores with solution of sodium hyposulphite was introduced by von Patera in 1858, and has been variously improved, notably by the substitution of the calcium salt for the sodium salt. This process, however, had some serious disadvantages, the two most important being the necessity for a high degree of chlorination and the recovery of the precious metals in the form of sulphides.

In order to get a satisfactory extraction it was necessary to chlorinate thoroughly, and this was not always possible, particularly in the presence of lime. Mr. E. H. Russell discovered, however, that the addition of a copper salt to the sodium hyposulphite solution, resulting in the formation of a cupreous sodium hyposulphite, largely increased the solvent power of the solution for the ordinary silver minerals in ores, so that it was not necessary to roast with salt so carefully or so thoroughly; or, with equal care in roasting, Russell's "extra solution," as it is called, will take out more silver than a plain hyposulphite solution. In other words, the use of the double hyposulphite increased the extraction of silver by the leaching process.

The Russell process can be applied to some ores without roasting, but in general the ores are roasted with salt. They are then charged into large vats and leached with water to extract soluble salts; they are then treated with a succession of hyposulphite solutions of varying compositions and strengths, according to the character of the ore, and are finally washed with water to displace the hyposulphite solution. The tailings are then run to waste. The

various solutions carrying the precious metals are gathered up in large vats and precipitated with sodium sulphide. This produces a precipitate of sulphides of gold, silver, copper, and a little lead. Most of the lead of the solutions is generally precipitated by a previous treatment with sodium carbonate.

The Russell process has been applied with marked success to the tailings of other processes, such as amalgamation and the old process of lixiviation with plain hypsulphite. Under favourable circumstances tailings can be lixiviated for 1.50 dols. to 2.00 dols. per ton.

The actual extraction of the silver by the Russell process reaches a high percentage of the total silver present in the ore. In one instance a mill treating nearly 23,000 tons a year averaged nearly 94 per cent. for the whole year. With tailings the extraction is not so high, being from 50 per cent. to 70 per cent.

Having brought the extraction of the silver from the ore up to a satisfactory figure there remains the question of dealing with the sulphide precipitate. For a long time this was admittedly the weakest point in the leaching process. After going through all the operations of crushing, roasting, leaching, and precipitating, the best we can say is that we have a rich concentrate which requires further treatment to convert the precious metals into saleable forms.

It is true these concentrates are often very rich and may carry a higher silver percentage than the bullion produced by many amalgamating mills, or even by amalgamating the same ores; but the silver, as well as the other metals, are chemically combined with sulphur, and they are also in bad physical condition, being dry powders, which are very susceptible to loss in handling, while their sampling and assaying present unusual difficulties.

The improvement in leaching introduced by the Russell process and the success of this process has stimulated the development of processes for refining the sulphides. In the early days several processes of dealing with the sulphides were proposed and some of them tried more or less; but the business finally settled down to sending the sulphides to the smelters for treatment, although this was well known to be troublesome and expensive. In 1891 Mr. C. A. Stetefeldt introduced, at the Marsac Mill, Park City, Utah, an unpatented process, which was built up out of the general fund of information available. This process consisted in matting the sulphides, grinding, roasting, grinding again and dissolving the copper out in dilute sulphuric acid, then melting the silver and crystallizing the bluestone. It did not yield fine bullion, but the bullion had to be refined as well as parted; besides, there was some loss. This process was thoroughly tried at the Marsac Refinery and then a year's run was made, the net result of which was that it did not prove sufficiently better than sending the sulphides to smelters.

In 1893 the Dewey-Walter Refining Company undertook the refining of the Daly sulphides in the Marsac Refinery by the sulphuric acid process, upon which a United States patent has been issued to the writer. Naturally difficulties were encountered in starting a new process, and much of 1893 was taken up in getting the process into smooth working order; but in 1894 a run was started in which all the regular sulphides produced by the Marsac Mill in 1894 were refined, and thus a complete set of statistics of the operation of the process was obtained.

Broadly speaking, the process consists of six main operations:—

First. Boiling the sulphides with strong sulphuric acid in an iron pot.

Second. Dissolving out the sulphates of copper and silver in a lead-lined tank, leaving a residue containing the gold and lead of the sulphides and also rich in silver.

Third. Precipitating the silver out of the filtered solutions by copper plates.

Fourth. Sweetening, drying, pressing, and melting the cement silver.

Fifth. Treatment of the solutions after the removal of the silver to crystallize the sulphate of copper and recover the excess of acid for re-use.

Sixth. Treatment of the gold-bearing residues.

The 1894 run of the Marsac Leacher produced 116, 519½ lb. of regular sulphides which were treated by this

process. For convenience they were divided into 25 lots mostly from 4,500 to 5,500 lb. in weight. As reported by the assayer of the Daly Mining Company, these lots varied in composition as follows:—

Composition, Daly Sulphides for 1894.

	Ag.	Au.	Cu.	Pb.
	Oz. Per Ton.	Oz. Per Ton.	Per Cent.	Per Cent.
Maximum ..	11,127.0	14.8	32.9	0.2
Minimum...	7,835.0	7.6	20.3	0.6
Average	9,877.4	11.225	27.17	0.33

The totals were—

Silver.....	572,544.4 oz.
Gold.....	646.1 „
Copper.....	31,585.3 lb.
Lead.....	355.86 „

The plant required is simple and all of it is well known. It is easily managed and no especial skilled labour is required. It consists of two ordinary iron pots such as are used in parting bullion; a series of 21 lead-lined tanks for dissolving, filtering the solutions, precipitating the silver and filtering off and sweetening the cement silver, together with crystallisers to recover the bluestone, and evaporators to concentrate the mother-liquors for re-use in the pot, a dryer and press for the cement silver, furnace for melting the bullion, four storage tanks for acid, and pumps for handling the liquids. The large pot for boiling the sulphides is 46 in. in diameter and 3 ft. deep. It is hung by its rim on a cast-iron plate and is enclosed in brickwork over a fire-box. It stands 14 ft. from the floor and is provided with a suitable hood and stack to take off the fumes. A smaller pot is used for boiling the residues. The tanks are arranged in steps to allow the descent of the solutions from the one to the other by gravity.

The process consists in boiling the sulphides in strong sulphuric acid to convert the sulphides into sulphates. The sulphate of silver is soluble in strong sulphuric acid, but the anhydrous sulphate of copper is practically insoluble. Owing to the large percentage of copper, averaging 27 per cent. in 1894, in the sulphides, a large quantity of insoluble sulphate is produced and this is one of the most serious difficulties of the process. After boiling, the charge is removed to the dissolving tank in which is put wash-water and weak solutions. Here the copper sulphate goes into solution along with the silver. The solution is filtered into the precipitating tanks where the silver is precipitated by metallic copper, after which the solutions are concentrated and go to the crystallisers to recover the bluestone. Periodically the cement silver is removed to the filter, sweetened, dried, pressed, and melted. The mother-liquors are concentrated, crystallised, and the recovered acid finally sent back to the pot. The residue in the dissolving tank is taken out, washed somewhat and re-boiled in acid to remove as much as possible of the silver that it contains.

Practical Operations.—A charge of about 975 lb. is put into the pot in the morning with about 1,000 lb. of 66° acid and thoroughly mixed and the charge heated. At first the reaction is rather violent, SO₂ is copiously evolved and the fumes carry much sulphur which gives them a yellowish colour. At this stage a steam jet may be required to increase the draught. After a while the reaction settles down and the normal charge boils quietly until near the end. As soon as the charge gets stiff, more acid, about 100 lb. is added, until about 3,000 lb. have been added. Toward the end, evaporated acid is used. As the boiling goes forward, anhydrous sulphate of copper is formed in large quantities which separate, forming a granular mass. This necessitates frequent stirring of the charge, and this in turn is hard on the pots. A network of cracks develops and finally the acid finds its way through, when the pot must be replaced. In the 1894 run nine pots were used, two of which were short lived. Better results have been obtained since.

The progress of the operation can be watched by taking out a small sample of the charge, treating with water and adding HCl to the solution, but this is not necessary after getting familiar with the process, since the colour changes

from black to brown or dark grey. About 90 per cent. of the total acid used is added before the charge begins to show soluble silver salts. Then the charge foams violently and must be constantly stirred while the fire must be lowered. In about an hour the foaming is over and the charge is finished. This usually occurs in the afternoon of the day after starting. On the second morning the charge is warmed up, generally with the addition of some acid and, as it is rather thick, it is ladled out into a trough which delivers it to the dissolving tank. The pot is then started on a new charge.

The dissolving tank is filled with cold water within 6 or 8 in. of the top and tightly covered, since the introduction of the charge generates much heat. After the charge is in, the cover is raised and the solution is stirred with a paddle and boiled with steam, after which it is settled and drawn into the filters. The first tankful of solution contains most of the copper. It is run into a small precipitating tank and kept separate from the rest of the solution. The charge now resembles thick white mud and is washed from 8 to 10 times with weak acid solutions to remove the silver, after which the residue is thrown into a filter. The residue varies very much, running from 5,000 to 19,000 oz. Ag. per ton and 50 to 100 oz. Au, the balance being mainly sulphate of lead.

The filters are 3 in.—4 in. of clean quartz sand on a foundation of lead plates, cocoa-matting and asbestos cloth, resting on lead strips, giving a space below. It is impracticable to settle all the very fine residue in the dissolving tank so some of it passes over into the filters and chokes them up. In about two weeks the filters must be washed by a stream of water from below and the muddy water pumped off the top.

The solution has a reducing action and immediately a separation of metallic silver begins in the dissolving tank, often with the formation of beautiful growths upon the surface of the liquid, and this reaction continues in the filters. By this reaction, metallic Ag is found in the first residue and some 10,000 oz. may accumulate in the filters during a year's run.

From the filters the solution goes to the precipitating tanks where the Ag is precipitated by copper, cathode plates from an electrolytic refinery being used. The first or copper solutions require a long time to precipitate, sometimes 18 hours, but ordinary solution is precipitated in 4—5 hours. During precipitation the solution is stirred by air and heated by steam. When the precipitating tank is cold and the hot solution of silver sulphate runs in, there may be a separation of silver sulphate, which may go into solution again as the solution is heated up, but some of it may also remain with the cement silver and be removed in washing the silver, in which case the wash water must be treated with copper.

When about 20,000 oz. of cement silver have accumulated in the precipitating tanks, it is removed to the sweetening tank and washed with hot water and then with acidulated hot water until the ammonia test shows no copper, which takes about 15 hours. The wash water runs through a guard tank containing scrap iron and then to waste.

The sweetened silver is put into sheet-iron pans, and dried about 24 hours in a steam dryer, pressed into cakes, dried again, and melted. In 1894 the melting was done in crucibles holding about 2,400 oz. or two bars; about a pound and a half each of borax and nitre were used to a crucible. The melted silver was poured into heated and greased light cast-steel moulds. After pouring, a little sugar was thrown on the liquid silver, and the mould covered by a tight-fitting cast-iron cover. This gives a very smooth surface to the bar. When cool the bars are hammered up and marked. The average fineness for 1894 was 999.4 silver with no gold. 446 bars were shipped, of which 401 were 999.5 fine and 45 were 999.0 fine.

The bluestone solution is concentrated to about 35° to 37° B., and run into ordinary crystallisers provided with lead strips, and allowed to stand two days or more, when it is pumped back to the evaporators, and run up to 42° B. It goes back to the crystallisers, and a crop of crystals containing iron and but little bluestone obtained. The solution goes back to the evaporator. The crystallisers are filled

with cold water, which dissolves most of the iron and only a little of the copper. This solution goes through the guard tank to waste. These bluestone crystals are very small, but it answers as well in the leacher in preparing extra solution. The mother-liquor is brought up to 50°—52° B., and then allowed to stand in a crystalliser several days to separate iron. It is then pumped to storage tanks for use in the pot. While concentrating considerable iron separates in the evaporators. Periodically this is washed out, and the solution run to waste through the guard tank.

After boiling five charges of sulphides, about 750 lb. of wet residue is obtained. This is put into the pot and boiled with a little more than its own weight of acid, after which it is washed and the final residue dried. This residue is very complex in composition, although it is mainly sulphates of silver and lead. There appears to be some acid sulphate, for the sulphuric acid present is far more than sufficient to form normal sulphates, and yet the sample is so dry that the excess of acid cannot all be free; it contains the gold of the sulphides. During 1894 this residue was shipped away to the smelters for treatment, but at the present time it is being melted on a hearth.

Supplies.—Sulphuric acid is received at the refinery in iron tank-cars holding 40,000—50,000 lb. It is stored in two lead-lined wooden tanks holding about 54,000 lb., and is elevated by a montejus to two iron receivers above the level of the pots, from which it is drawn to the feed pots. In the 1894 run, 389,459 lb. were used, being an average of 3.34 lb. per lb. of sulphides treated, or 0.68 lb. per oz. of silver. Copper to precipitate the silver is used in the form of cathode plates, and 16,832.5 lb. were used, 1 lb. of copper precipitating 2.7 lb. of silver or 33.1 troy oz. The ordinary local coal is used, and 159,000 lb. were used in the 1894 run.

The regular labour required was a superintendent and two men with an extra man to assist the superintendent in melting bullion. Occasionally some extra labour was required, particularly in shipping residue, and making the annual clean-up. Mechanics were also required for special work occasionally, but the lead-burning was done by one of the regular men.

Returns.—It is a well-known fact that, in assaying, some of the precious metals pass into the slag, and some are absorbed by the cupel, causing a loss in the determination. In the case of ordinary ores, this quantity per ton is generally small, although the percentage of the total silver is large. In the case of rich materials, however, the percentage is low, while the actual quantity per ton becomes considerable, and when the rich material carries copper, the loss of silver per ton becomes quite respectable. In our business transactions, the sulphides are always settled for upon an assay corrected for slag and cupel absorption which shows from 100 to 200 or even more oz. per ton more than the ordinary uncorrected assay shows. Even on the corrected assay, the actual amount of silver returned by the refinery on the year's work was 2,073.81 oz. more than the assays called for, showing very plainly that even the corrected assays do not show all the silver really present. This silver was divided as follows:—

116,519.5 lb. sulphides contained 572,544.45 fine oz. of silver.

Product Returned.

	Fine Ounces of Silver.	Per Cent. of Total Silver.
Fine bullion, free from gold	551,329.89	96.29
Residue	15,773.41	2.76
Clennings	5,328.87	0.93
On hand	2,191.00	0.38
Total	574,623.17	100.36
Plus clean up	2,073.81	0.36

It is regarded as an extraordinary showing for a chemical process on the large scale to recover more than the best assay possible calls for.

As to the recovery of gold, I cannot see any reason why it should not equal the silver recovery, but the figures upon the point are not satisfactory. The actual return of gold

for the year was 606.9 oz. The original assays of the Daly Mining Company called for 654.8 oz., but their re-assay on some of the samples reduced this to 616.1. This left an apparent shortage in the returns of 39.2 oz. The same samples were assayed by Mr. Chas. Earle under my direction, and while the silver results showed a satisfactory agreement with the Daly assays, yet his gold determinations called for only 602.9 oz., showing a plus clean up on the year's work of 4 oz. After the close of the year's business a general sample was prepared by taking proportionate weights of each of the check samples of the 25 lots. The Daly Company's assay of this sample called for 616.9 oz., and showed a plus clean up of 1 oz. Mr. Earle is no longer with me, so I cannot add his figures on this sample. There are especial difficulties in determining such small quantities of gold in the presence of so much silver.

The conditions of the process are such that I do not see how we could gain so much on the silver and lose on the gold, so that I am satisfied that the process practically recovers all the gold that goes into the operations, although the assays may not always show this.

The bluestone produced amounts to 175,809 lb. or 3.63 lb. per pound of copper, including the copper in the sulphides and the copper used to precipitate the silver. About 125,000 lb. of bluestone were used by the leacher in preparing extra solution, leaving 50,000 lb. to be sold to outside parties. No particular care is taken to prepare fine large crystals of bluestone, and it is not necessary to purify the solutions from iron except as above described. Most of the bluestone derived goes to the leacher, and the size of the crystals is of no moment whatever, while the small amount of iron present does no harm. The best grade showed 0.34 per cent. of protoxide of iron, the medium 0.69 per cent., and the worst, of which only a small quantity was produced, 3.87 per cent.

The following table summarises the statistics for the year:—

THE 1894 RUN OF THE MARSAC REFINERY, WORKING BY THE DEWEY-WALTER PROCESS OF BOILING RUSSELL SULPHIDES IN STRONG SULPHURIC ACID.

First charge of 1894 sulphides to pot, February 20, 1894.

Plus clean up.....	2,073.84	0.36

All weights of sulphides and products, excepting one covering less than 200 oz., and all the assays are the originals made by the Daly Mining Company.

The advantages of this process are the phenomenal percentage of silver removed, and that it is an entirely liquid one from beginning to end, so that there is no loss from handling dry products. There is no roasting to cause loss. A large percentage of the silver is recovered as very fine bars, ready to enter the market. It is so simple and so easily carried out, and the plant is so small and inexpensive, that it can be installed at individual leaching works.

Finally, the cost of operating is small; in fact, the value of the bluestone recovered returns a large proportion of the operating expenses.

I.—PLANT, APPARATUS, AND MACHINERY.

Autoclave of A. Pfungst, Report on the, by Noetting and Freyss. H. Groscheintz. Bull. Soc. Ind. Mulhouse, 1895, 261—262.

REFERRING to the report (Bull. Soc. Ind. Mulhouse, 1895, 88—91; this Journal, 1895, 769), the author points out that he devised a stopcock for an autoclave in Wurtz's laboratory similar to that described by Pfungst, but which was subsequently modified as follows:—Instead of the screw B

* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reader Luck, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

terminating in a flat plate, it ends in a point P, which passes through a hole in the washer R. By this means the tube can be unscrewed under all conditions, to enable gas to escape between the point P and the washer.—T. A. L.

PATENTS.

Fluids, Cooling and otherwise Treating: Improvements in or relating to Apparatus and Processes for. J. Klein, Frankenthal, Rheinpfalz, Germany. Eng. Pat. 2452, Feb. 1, 1895.

THIS is an apparatus for cooling or otherwise treating fluids, provided with natural, ventilating, or any other draught. It consists of two or more upright or nearly upright dividing elements placed over each other and made of separate cooling-walls consisting of strips of board or laths, laid in close proximity one above the other, so that the air has free access to them on all sides, and the fluid descends only very slowly.

The fluid to be treated trickles down over the surface of the laths, and is thus made to expose a very large surface to the cooling, or other action, of air, or gas, passing through the spaces between the laths.—R. B. P.

Retort [Annular] for Chemical Processes, An Improved. E. L. Pease, Stockton-on-Tees, and Ashmore, Benson, Pease and Co., Ltd., Stockton-on-Tees. Eng. Pat. 2946, Feb. 11, 1895.

THE retort consists of a combined inner and outer casing *b, a*, the annular space between them forming the chamber *c*, in which the material to be treated is placed. Asbestos packing, *n*, is preferably provided at each end to render the retort steam-tight. The inner cylindrical casing is supported by the retort lids *d*, which are held in their places by

set screws *e* working through resistance bars *f*. A jacket or envelope of perforated material is employed, and may be corrugated, or the casing may have ribs or ridges. Steam or air is passed alternately through the tube *g* to a passage *h*, and, after passing through the materials (heated to a high temperature in the retort), arrives at the cavity *m* and escapes through the tube *l*. In one modification, the discharge pipe *l* returns through the centre of the inner cylinder and discharges at the same end as the inlet for air or steam; in another modification, the inner casing is supported at one end within a closed end of the outer casing. The claim is for "A retort consisting of an annular chamber formed between an inner and outer casing adapted by their construction and arrangement of parts, to pass steam or air through the material contained in the chamber with equal or uniform penetration of the mass."—R. S.

Filtering Liquids, Improvements in and relating to Apparatus for. H. H. Lake, London. From A. A. Pindstoffe, Copenhagen. Eng. Pat. 6028, March 22, 1895.

IN this apparatus the filtering medium (sand or the like) is arranged between two vertical concentric cylinders of fine wire gauze.

The liquid to be filtered is admitted to the inside of the inner gauze cylinder, and flows outwards through the filtering medium into an outer containing casing provided with an exit pipe.

It is claimed that by this arrangement the difficulty experienced with filters in which the filtering medium is in a horizontal layer—namely, that it becomes clogged with sediment—is obviated.—R. B. P.

Asbestos Filters, Improvements in. C. D. Abel, London. From B. Blumenfeld, Vienna. Eng. Pat. 24,887, Dec. 28, 1895.

THIS invention relates to improvements on the filter described in Eng. Pat. 5377, 1890 (this Journal, 1890, 796), in which the filtering layer of asbestos is formed on the outer surfaces of the porous walls of flat, hollow bodies that are enclosed, in greater or less number, within a filtering chamber, with which communicates a supply-pipe for water to be filtered. The first improvement consists of washing devices for cleansing the filter elements from the accumulated deposit. Two forms are described:—1st. Jet pipes are arranged between the filter elements, and are connected together by cross pipes, to which are fixed the water-pressure pipes working through stuffing boxes in the casing. The tube-rinsing frame thus formed receives an up-and-down motion, as by means of a rack and pinion. 2nd. Jet pipes are carried by a tubular shaft mounted in bearings in the filter casing and connected to the water-pressure supply, the shaft receiving a reciprocating rotary motion for causing the jet pipes to swing up and down over the surfaces of the filter elements. The second improvement consists in providing the inlet and outlet branches at the base of the collecting chamber with the hand wheels of the valves arranged all at the same height for convenience of working.—R. S.

Non-corrosive Compositions for Coating Boilers and the like to Resist the Action of Heat and Atmospheric Influence, Improvements in. T. Lowe, Nottingham. Eng. Pat. 8478, April 30, 1895.

THE composition consists of a mixture, formed preferably in the following proportions:—Water, 15 per cent.; gas tar, 5 per cent.; oak extract, 30 per cent.; carbon blacking, 10 per cent.; and plumbago, 40 per cent.—R. S.

Furnace Pans, Coppers, and the like, Improvements in and connected with. J. Wood, Ipswich. Eng. Pat. 18,464, Oct. 3, 1895.

RELATES to removably arranging furnace pans, coppers, and the like, instead of cementing them in as usual, whereby easy access may be had to the flues, &c. There is provided a metal, earthenware, or other suitable bushing, lining, or flange around the orifice in the brickwork or masonry for the reception of the flange or rim of the pan, &c., arrangements being made for forming a tight joint, and also, by means of handles or other devices, for facilitating the removal of the pan, &c. when desired.—R. S.

Pumping Gritty Fluids, Improvements in the Method of and Apparatus for. W. Jordan, London. From The International Contract Company, Syracuse, U.S.A. Eng. Pat. 18,825, Oct. 8, 1895.

THE apparatus is especially intended for use in dredging operations, where it would be placed in a boat floating in the water, the suction pipe being arranged to draw the mud from the bottom of the water. The drawings illustrate apparatus intended for this purpose. The principal improvements are: (1st) Cleansing the walls of the pumping cylinder by discharging a film of water past the edge of the piston during the forcing stroke; (2nd) Forcing water into both of two connected cylinders above the pistons with a pressure exceeding the resistance below the same; (3rd) Actuating the two pistons alternately by water pressure or by mechanical agency, and providing special constructions for the valves and pipe connections to prevent concussion in the pipes or the settling of the sand therein; (4th) Arranging a force pump with a suction pipe immersed just below the surface of the water, to obtain clean water for use in actuating the pistons; (5th) Using two vertical cylinders, and passing the clean water alternately into them by means of a shut valve; (6th) Discharging the clean water from the upper end of each cylinder back to the water level; (7th) Preventing the clogging of the suction pipe by employing a sieve around the nozzle thereof, and automatically supplying its upper end with clean water.—R. S.

Refrigerating or Cooling Machines, Improvements in or relating to. W. P. Thompson, London. From A. T. Ballantine, Cleveland, Ohio, U.S.A. Eng. Pat. 20,922, Nov. 5, 1895.

This invention relates to refrigeration or cooling machines, in which refrigeration is produced by allowing a volatile liquid, such as anhydrous ammonia, to expand into gas in a refrigerating coil, from which the gas is continuously removed by means of a pump.

The inventor states that it is impossible by the means hitherto employed, automatically, to keep the refrigerating coil always full of gas only, which is indispensable. The essential part of the invention consists of a feed valve, controlled by an elastic diaphragm, loaded by means of a weighted lever. The pressure in the refrigeration coil acts upon the feed valve through the diaphragm, and allows a jet of ammonia to enter the coil when the pressure falls to a certain extent, and then closes it again as the pressure rises through the expansion of the ammonia into gas.—R. B. P.

Generating and Applying Vapours, Improvements in the Method of and Apparatus for. O. S. Rhodes, East Stroudsburg, U.S.A. Eng. Pat. 23,701, Dec. 10, 1895.

The apparatus consists of a combination of a furnace, boiler, and engine. The furnace is surmounted by the boiler, and has an engine cylinder on each side of it. The boiler consists of a vertical outer shell, up which the furnace gases pass to the stack, and containing three tubular supports connected together and provided with projecting horizontal tubes closed at their outer ends. These supports open above into a receptacle, also contained within the casing, which, as well as the supports and projecting tubes, is filled with a suitable heating liquid, preferably of high boiling point, as a fixed oil. Within the receptacle is a closed chamber containing a volatile liquid, as ether, the vapour of which is to be used in the engine, and which is heated by the oil, &c. in the outer receptacle. The supply pipe for the volatile liquid passes up the centre of the central tubular support above mentioned, while the vapour given off passes down two tubes which reach nearly to the top of the closed chamber and extend down the central tubular support, and thence pass to pipes having valves leading to the engine cylinders. The engine cylinders themselves have jackets through which the boiler liquid circulates. The exhaust from the engines passes to a condenser, and is then forced by a pump back to the closed chamber.—R. S.

Mill for the Grinding and Emulsification of Vaccine Material, Flesh, Drugs, and other Substances, An Improved. M. J. F. Schutte, Haarlem. Eng. Pat. 23,760, Dec. 11, 1895.

This invention consists of a special arrangement of pestle and mortar, formed of hard substance, as of porcelain or of glass. The mortar is carried within a frame, having gearing to allow the pestle to be rotated by hand or by power, and is shaped so that it and the pestle accurately fit one another. In one form the pestle is somewhat conical, ending in a blunt cone, and provided on its surface with spiral channels wider at the top than on the under surface, where they gradually disappear. In another form the pestle has a hemispherical end, and touches the mortar only at such end, the sides of the pestle and mortar above that part being coned in opposite directions, while the spiral channels on the pestle only reach to about half of the hemisphere. In the case of vaccine material, the latter is mixed with a suitable quantity of glycerin and distilled water, and placed in the mortar, and in a short time perfectly emulsified. The upright carrying the pestle is so constructed that it and the pestle may be removed from the mortar.—R. S.

Vapour Condensers, and Apparatus for Destroying Noxious Fumes, Recovering By-Products from Distillation and like Purposes, Improvements in. S. G. Merrick, Philadelphia, U.S.A., and H. L. Washburn, New York, U.S.A. Eng. Pat. 25,001, Dec. 31, 1895.

A METALLIC casing is divided by a vertical partition into two compartments, each of which is charged with suitable

absorbent liquid to, say, two-thirds its height. A horizontal shaft, driven by power, passes completely through the centres of both compartments, and carries a series of coiled pipes, having at the ends which are in the chamber receiving the gases, &c. from the stills or other source of supply, bell-shaped mouths so formed that when they strike the surface of the liquid during rotation they shall be parallel to that surface. Each time one of these mouths strikes the liquid surface a portion of the gas or fumes is entrapped, and forced by the water through the coil to the second chamber, where it escapes if uncondensed, and may be led away or returned to the first chamber.—R. S.

II.—FUEL, GAS, AND LIGHT.

Electric Furnace for 1,000 Amperes. J. Pfleger. Zeits. f. Elektrochem. 2, 367—368.

This furnace, which is crucible-shaped, may either be lined entirely with magnesite (M) or with magnesite above and with graphite (G and C) below. The current is led in by thick carbon rods. The negative carbon (D) is fixed underneath. The positive carbon D passes through the lid H and can be moved up and down by the winch N O; this serves to vary the length of the arc according to the available E.M.F. Materials are fed in through the funnel

T. The gases evolved during the process travel through the canal J as shown by the arrows, and pass out through the aperture L either into the open air or to the chimney. Any solid matters carried with the gases are deposited in the canal J and can be removed by withdrawing the slider K. The fused materials are withdrawn through the hole P, which is otherwise closed by a carbon stopper. The furnace should be mounted so that the negative carbon can be got at and renewed. A sheet, c, of asbestos, 9 mm. thick, is introduced between the plate b and the iron plate a. The mechanism of the winch is insulated at the points x x x.—D. E. J.

Calcium Carbide, The Manufacture of. J. T. Morehead and G. de Chalmot. J. Amer. Chem. Soc. 18, [4], 311—331.

By means of the plant herein described, the Willson Aluminium Company produce calcium carbide, the dynamos

being worked by water-power—a 300-h.p. wheel under 28 feet fall.

The furnace employed at the Spray (N.C.) Works is shown in section in Fig. 1. It is of brick, the front being

Fig. 1.

closed by four iron doors one above another, and measures $2\frac{1}{2}$ by 3 feet inside at the base. The lower electrode is an iron plate *a*, covered with 8 ins. of carbon *b*, composed of pieces of carbon pencil, or a mixture of coke and coal tar, and connected with the dynamos by 16 copper cables, *c*, of $\frac{3}{4}$ in. in diameter. The upper electrode, *d*, consists of a copper bar 3 ins. square, *h*, carrying the carbon holder *f*, to which are attached the carbon pencils *e*. There are six of these, each 4 ins. square and 36 ins. long, arranged in pairs and cut so as to dovetail into the holder, and are surrounded by an iron jacket, *g*, to prevent undue wasting by oxidation. 16 cables complete the electrical circuit, and the whole electrode, being suspended by a chain passing over pulleys, can be raised or lowered at will by means of the hand wheel, *K*, working on the screw, *i*, at some distance away from the furnace. The attendant watches the volt- and ammeter, and regulates the screw accordingly, and the height of the piece of carbide formed in the furnace can be gauged by measuring the descent of the screw.

For the Niagara Falls Works the improved furnaces shown in Figs. 2 and 3 have been constructed. In order to allow of continuous working, an iron car, *a*, running on a track and forming with its interior layer of carbon the electrode, is substituted for the bottom of the furnace. The upper electrode contains double the number of carbon pencils in the older form, and is about twice as heavy, necessitating the use of a stronger bar, made up of two outer slabs of iron, 6 ins. by 1 in., and a central one of copper, 6 ins. by $1\frac{1}{2}$ ins. The holder is divided into two pieces, *m* and *n*, dovetailing into one another, so that the lower can be slid on to the upper from the car. As sometimes an arc will be started between the group of pencils and the holder, resulting in the partial fusion of the latter, a lining of removable iron plates, *q* (Fig. 2), is interposed between them. Connection between the dynamo cables *Q* and the car is made by means of a clamp *p*, which can be tightened round the projection *Z*, by means of the screw *s* (Fig. 2).

The car being run into the furnace, the upper electrode set in position, and the current switched on, the mixture of coke and lime is fed into the car through the shoots *e*, which extend the whole length of the car, the supply being regulated by the rate of motion of the 4-bladed feed-rods *f*. Automatic stoking, to fill up the holes made in the loose material by the evolved gas, is effected by means of a rod *g* (Fig. 3), attached to the car and moved backwards

and forwards for a couple of inches 20 times a minute, pulling the car with it. This motion also increases the efficiency of the arc by preventing its tendency to become localised.

Fig. 2.

The rod *g*, may also be used for making the connection with the dynamo cables, and is then composed of an iron and a copper bar.

Fig. 3.

The furnace is entirely closed, the door *c* (Fig. 3) being shut at the outset, and the safety door *n*, is also closed as soon as the issue of flames indicates that the furnace is filled with carbon monoxide. The gases escape through a chimney *V*, at the side, and therefore the top portions of the upper electrode are not exposed to the heat, the temperature being also kept down by the circulation of cold air through the jacket *W*, from the intake *X* (Fig. 2), to the chimney *y*.

The arc is kept steady by being covered by the coke and lime for a height of a foot around the pencils, the latter being raised by the attendant at the hand wheel when the voltage becomes low. The operation goes on for several hours, and results in the formation of a conical block of calcium carbide, about 2½ ft. in height, occupying the space between the electrodes, but never quite filling up the whole furnace room, there being always a certain amount of lime and coke left intact and in a loose condition, so that it is easily separated from the carbide and may be returned to the furnace. Covering the carbide block is a thin crust consisting chiefly of carbon, but also of carbide and lime, and seldom exceeding 7 per cent. of the weight of the block or yielding more than ½ eb. ft. of gas per lb. The carbide is crystalline, the crystals being more perfect with an excess of coke, low voltage, and slow cooling. Carbide of average quality (about 5 eb. ft. of gas per lb.) is often coloured red, especially if high voltage is used; the low qualities are often grey or blackish, with streaks of graphite.

The coke used should contain about 7, with a maximum of 10 per cent. of ash, or the effect on the quality of the carbide is prejudicial. It should be ground fine enough to pass through a 50-mesh sieve. The lime need not be so fine, but the coarsest pieces must pass through a 10-mesh sieve, or the carbide will be of inferior quality. The lime should not contain more than 3 per cent. of magnesia at the outside, this substance being especially detrimental, probably by forming a film between the carbon and the lime, and so preventing combination. In the lime used at the Willson Works only 1½ per cent. is present, and 1 per cent. of other impurities.

Intimate mixture of the lime and carbon is necessary for the attainment of good results. The uncombined mixture in the furnace may be used over again, but as the impurities and ash from the combined portions are left behind therein, an admixture of charcoal is advisable. Being red hot on leaving the furnace, the mixture will lose much of its carbon if left in the air, and should therefore be used up again as quickly as possible or stored in iron bins. The loss of carbon is greater in open furnaces and with slaked lime, water-gas being evolved in the latter case.

To preserve the carbon pencils of the electrode from wasting, it is advisable to protect them in open furnaces by a surrounding cover of iron, packed with a mixture of coke and pitch; they will then last about 100 hours with intermittent working with a 1,700–2,000-ampère current, or 200–300 hours if the operation is continuous, the waste chiefly occurring after the current is shut off and the pencils exposed. About 8,500 lb. of carbide can be made with one set in the open furnaces.

The gas-producing power of the carbide is tested by breaking up a block and placing about 1 to 3 oz. of average sample in a dry bottle. Water is dropped in through a funnel and the evolved gas conveyed to a meter through cooling tubes.

The lime in the mixture is roughly determined by boiling 2½ grms. with hydrochloric acid and titrating the solution; the coke, by filtration from hydrochloric solution, and weighing.

The practical limit to the height of the carbide blocks is reached at about 2½ ft., the loss of voltage, averaging 6 volts per foot of carbide, beginning thenceforward to reduce the efficiency of the furnace.

Tables are given showing the strength of current, horse-power, and time employed for various runs, together with the loss of voltage, the yield of carbide per horse-power per 24 hours, and the production of gas on the same basis, both with unslaked and air-slaked lime. The averages—

	Net Production per H.P. in 24 Hours.	Cubic Feet of Gas per Lb.	Cubic Feet of Gas per H.P. in 24 Hours.
Unslaked lime	9.75	4.97	48.33
Slaked lime	7.51	5.27	39.52

show to the advantage of the former, which, besides, is less bulky, and the unused mixture cools faster when removed from the furnace. On the other hand, unslaked lime has to be ground, and requires more stoking to keep the mixture up against the pencils when in the furnace.

To obtain a carbide yielding about 5 eb. ft. of gas per lb. (which is found to produce the largest amount of gas per horse-power), the mixture should consist of 64–65 parts of carbon per 100 parts of lime, rather more if the voltage is increased and *vice versa*. A large proportion of carbon gives purer carbide, but also more coating. The yield of carbide varies in inverse ratio to the quality, the extremes of a series of experiments made with slaked lime and with a current of 65 volts and 1,700–2,000 ampères being 7.10 lb., yielding 5.80 eb. ft., and 10.52 lb., yielding 4.23 eb. ft. of gas per lb. The best yield of gas per horse-power was obtained with a 100-volt current and 1,760–2,000 ampères with a 6-pencil electrode, it being found that higher ampérage causes the pencils to waste quickly, and also entails greater loss of voltage. On the other hand, high voltage lowers the quality of the carbide and makes a thin block, the action of the current not spreading out so far into the mixture as when the voltage is about 65.

Although theoretically 0.563 lb. of carbon and 0.875 lb. of calcium should yield 1 lb. of carbide, it is found, on the average of 10 experiments, that the proportions are higher in practice, viz., 1.228 lb. of CaO and 0.837 of C, both substances being volatilised or burned to some extent in the furnace, the carbon suffering the greater loss. If properly stoked and the arc kept covered, the consumption of material is lessened, and it is anticipated that the new furnace (Figs. 2 and 3) will give better results than those mentioned above.

Of other carbonaceous materials suitable for use in making carbide, charcoal yields a very pure product, but is costly and easily carried away by the evolved gas, some 10 per cent. extra having to be used on this account. Both soft coal and anthracite gave carbide, producing much smaller amounts of gas per horse-power in 24 hours than obtained by the use of coke, the superiority of this material and carbon over anthracite being probably due to their porosity facilitating that volatilisation of the carbon which is perhaps essential to the reaction.—C. S.

PATENTS.

Water, Producing Gases from, An Improved Process of and Apparatus for. J. H. Dunn and J. Parsons, both of London. Eng. Pat. 1707, Jan. 21, 1895.

The inventors propose to resolve water into its constituent gases by the action upon it of an electric current, the latter passing between the opposing ends of a pair of carbons, or other conductors, arranged after the manner of those of an arc lamp.

The carbons pass through insulating stuffing boxes, placed diametrically opposite one another, along the sides of a cylindrical vessel horizontally disposed. This vessel contains sufficient water to completely cover the carbons, and the level of the water is kept uniform throughout the process.

When the current passes, oxygen and hydrogen are evolved, from the positive and negative conductors respectively, and the gases are received into the bell-shaped ends of two tubes, which pass through the cylinder, and reach nearly to the ends of the conductors; the tubes lead to two gas-holders.

The heat produced by the current causes steam to be given off from the water, and this steam may be conducted away by a third tube; or, the exit tubes being closed by suitably placed cocks, it may be confined, until it attains a useful pressure.—E. R. B.

Water-Gas Carburettors, Improvements in Fittings for. S. Cutler, London. Eng. Pat. 4505, March 2, 1895.

In certain of the processes for carburetting water-gas, oil is sprayed upon the highly-heated refractory and non-porous internal surfaces of the carburettor in order to effect the vaporisation of the oil. To increase the area of such surface, the inventor places rolled, pressed, or cast steel bars of square, rectangular, oval, triangular, or corrugated section, in tiers, within the carburettor, each tier being "placed angularly" to those above and below it.—E. R. B.

Artificial Fuel, Improvements in Apparatus for Use in Manufacture of. G. Hayercraft, Pontardulais, Glamorgan. Eng. Pat. 5860, March 20, 1895.

To ensure regularity in the mixing of fine coal and pitch which are to be made into briquettes, the small coal is fed from a hopper on to the higher end of an inclined tray, which is hinged to the upright that supports the hopper. The pitch is similarly fed from a hopper on to a shorter inclined tray overlying the coal tray for a portion of the length of this latter. The pitch tray is hinged to the upright supporting the pitch hopper. The free ends of the trays hang in a stirrup which is pendent from a revolving crank, so that the trays are jiggled in order to facilitate the flow of the materials from the hoppers, and to ensure the intermixture of the pitch and coal when the former flows on to the latter in the lower tray. The mixture is finally discharged into the pug-mill.—A. G. B.

Gas for Lighting Purposes, Improvements in the Method of and Means for the Economical Use of. T. Rowan, London. Eng. Pat. 6027, March 22, 1895.

THE apparatus proposed is essentially a regenerative Argand burner, having a ring, the gas orifices of which are spaced at about 0.5 diameter apart, centre to centre (this would give about one-third the number of orifices present, in an ordinary Argand burner of like diameter). There are two chimneys, and the air, which is to support the combustion of the flame, passes down, between the outer and inner chimneys, becoming warmed. The cylindrical space between the chimneys, is closed at the bottom, and the warmed air finds exit by apertures, in the gallery supporting the inner chimney, and is, by them, conducted into a conical chamber, which surrounds the burner ring. This chamber is open at the top, and warmed air is therefore supplied, to either side of the ring of minute flames which arise from the burner.

It is claimed that the heated air has an attenuating effect on the flames, causing them to spread out and become more filmy, occupying, thus, the blank spaces intervening between the flames; and that the careful regulation of the heated air supply results in great economy as to illuminating effect produced. Thus, it is stated that, with an ordinary Argand burner, protected by a single chimney, and having a ring, 1 inch in diameter, provided with 36 gas orifices, and a single chimney burning 5 cb. ft. per hour, of 16 candle-power gas, a light of about 12 caudles is obtained, while, under like conditions, the patentee's burner gives a lighting effect of 35 caudles.

Several modifications of the structure of the burners are mentioned and also methods of telescoping the chimneys, with the object of controlling the draught more efficiently. There are also provided means whereby the gas is not allowed to become too hot before it reaches the place where combustion takes place.—E. R. B.

Carburetting Air and Gases, Improvements in. L. M. Bullier, Paris. Eng. Pat. 1953, Jan. 28, 1895.

THE single claim of this inventor is as follows:—"The admixture of acetylene with gases generally, for imparting or increasing illuminating power, substantially as specified." Apparently the rendering luminous of non-illuminant gas—such as air—is a feature to be specially noted; the inventor remarking in this connection: "I would observe that, although I have mentioned the application of acetylene to water-gas by way of example, it should be understood that the invention is applicable for carburetting air and non-

illuminating gases of every description, as well as for increasing the illuminating power of ordinary lighting gas."

—E. R. B.

Carbides or Acetylides of the Earth Metals and Alkali-Earth Metals, and Oxides or Salts of those Metals, Process for the Manufacture of. L. M. Bullier, Paris. Eng. Pat. 2820, Feb. 8, 1895.

By heating 56 parts of quicklime mixed with 36 parts of sugar-charcoal, wood-charcoal, lamp-black, or other variety of carbon, in an electric furnace, such as that of Moissan, a fluid product is obtained, which forms, upon cooling, a dark-coloured crystalline mass, corresponding to the formula C_2Ca . Similarly may be obtained the carbides of Ba and of Sr, as also those of Ce, Th, La, and other rare earth-metals.

Upon submitting the carbides, so obtained, to the action of water, acetylene is evolved, and the hydrated oxides of the various metals remain as by-products, 1 kilo. of C_2Ca yielding 300–350 litres of C_2H_2 .

Carbonates "or any other salt of the metal" may be substituted for the oxide: and, by treating the residual hydroxides with suitable acids, the inventor claims that the by-products of the manufacture may be recovered, in the form of useful substances.—E. R. B.

Acetylene and other Gases rich in Carbon, Improved Method of rendering suitable, for Lighting and Heating Purposes. L. M. Bullier, Paris. Eng. Pat. 6101, March 23, 1895.

THIS patentee now states (but see preceding abstracts) that, though acetylene may, theoretically, be diluted with air to give an illuminant, yet that, in practice, such mixtures are dangerously explosive, and, even when burnt under pressure, liable to fire back and to cause serious accidents. He therefore proposes to dilute acetylene with inert gas, and especially recommends, for the purpose, nitrogen, which latter may be prepared by any suitable process. A mixture of equal parts of acetylene and nitrogen "gives good results for lighting purposes."

The patentee remarks that, "the illuminating power of the acetylene is in fact much greater when that gas is diluted with an incombustible gas than when it is diluted with combustible gases, the lighting power of acetylene when mixed with a combustible gas being, theoretically, inversely proportional to the quantity of heat given off by the combustion of the combustible gas."

According to the patentee, the object of the dilution of the acetylene is to increase the surface of contact, between the oxygen of the air and the acetylene gas about to be burnt.

—E. R. B.

Filtering Water from Washed Coal or like Mineral, Means for, and for Recovering Coal or like Mineral from such Water, Improvements in. C. Craig, W. Craig, and G. K. Craig, Sacriston, Durham. Eng. Pat. 6365, March 28, 1895.

BETWEEN the washing machine and the waggens into which the coal is to be loaded is interposed a filtering or draining apparatus, which consists of a receptacle into which the washed coal and the washing water are discharged. The bottom of the receptacle has a central door, and is covered with coke-breeze to the depth of about one foot to serve as a filtering material. An axial screw shaft, with attached guides, carries radial arms which serve as harrows, and are designed to bring the coal to the basal opening when the shaft is revolved; the coal can be thus directly loaded into waggons, for the screw thread on the shaft causes the harrows to descend at each revolution. Better filtration than has been previously attained is claimed for this apparatus.—A. G. B.

Carbonic Acid Gas, The Separation of, from the Products of Combustion or other Mixed and Less Soluble Gases, An Improved Process and Apparatus for. H. S. Elworthy, Baudra, Bombay, India, and P. D. Henderson, London. Eng. Pat. 7284, April 9, 1895.

COMBUSTION gases are passed through an oxidising furnace, to convert carbon monoxide into dioxide, then through a scrubber to remove sulphur dioxide, and they are then taken

to a gas-holder or direct to a compressor, whence they are forced into a strong iron vessel charged with water, which absorbs the carbonic acid, and gives it off again on release of pressure, or on being run into a suitable separator. The combustion gases may be enriched by passing some carbonic acid gas through the furnace along with the air, which, by producing incomplete combustion, yields gases rich in carbon monoxide, giving after oxidation, gases containing from 30 to 35 per cent. of carbonic acid.

A strong horizontal cylinder is fitted internally so that the water forced in at one end under pressure (the gases being admitted at the opposite end) may in its course have an up-and-down movement. To aid the intimate contact of gases and the water, discs of wire gauze are secured between the partitions to a revolving shaft. The separator, to which the gas-charged water is taken, is a closed cylindrical vertical chamber, with safety-valve, &c. A transverse perforated plate is fixed near the top, and another similar plate near the bottom, the space between being filled with flint. The water rushes into the upper part through a jet, as spray, against the sides of the vessel and the perforated plate, and the gas, which is rapidly discharged, may be taken, through a drier if desired, to a gas-holder.—E. S.

Furnaces Suitable for Consuming House, Trade, and other Refuse, Improvements in. J. B. Allott and J. McCulure Paton, Nottingham. Eng. Pat. 8748, May 2, 1895.

See under XVIII. B., page 289.

Liquid Fuel, An Uninflammable Burner or Wick Cap for. C. Bourbott, Berlin, Germany. Eng. Pat. 479, Jan. 7, 1896.

THE wick cap consists in an annular metal piece surrounded by asbestos which is of the right width to exactly cover the space in which the annular wick of the lamp is held. The

cap is best held in position by a spring attached to a bridge of the cap and a bridge in the burner tube. The oil sucked up by the wick saturates the asbestos and there burns, thus heating the embedded metal, which is in this way maintained at a temperature high enough to gasify the oil and to thus obviate smell. To extinguish the lamp, the wick is turned down until it is no longer in contact with the asbestos. A similar cap may be applied to a flat-flame burner.—A. G. B.

Treating Liquids by means of Heat [Oil-Gas, and Conversion of Heavy into Light Petroleum], Improvements in Apparatus for. S. Pitt, Sutton, Surrey. From La Société Internationale des Procédés Adolphe Seigle, Levallois Perret, France. Eng. Pat. 18,518, Oct. 3, 1895.

THE proposed apparatus affords means whereby any liquid may be submitted to a series of heatings, thus assisting the latter in giving rise to new liquid or gaseous products. It is useful therefore for the production of oil-gas, and by its means also, the heavy petroleum may be converted into light ones.

The apparatus consists essentially, as shown in the figure, of a series of shell-like elements, A, A¹, A², which together form the wall of a combustion flue. Through the flue, there extends the flame of a liquid fuel burner L, the fuel supply of which is regulated automatically, by the variations of a pyrometer, M. R, B, are two further flues, the one enclosed within the other, and it is by their means that the heated gases of combustion are conducted away, in the directions indicated by the arrows.

Liquid, to be subjected to treatment by heat, is pumped by the action of P, from the reservoir K, through 2, into the hollow wall of the inner flue of B, thence, by B², it passes to the hollow walls of the elements, A², A¹, and A

traversing them successively, by means of the connecting tubes C¹ and C. E is a surface cooler, and U, a washer containing water, and through them the gas manufactured successively passes, having left the heating part of the apparatus, *vide* D.

The shells or elements, A, A¹, A², are of somewhat complicated structure, the space between the inner and outer walls of each being divided, by longitudinal partitions, into as many chambers as there are partitions; the liquid to be heated has to traverse all of these chambers, so that its course is to and fro in the wall of each element, until it arrives in that one of the chambers which contains the exit tube leading to the next element.—E. R. B.

Fine Fuel, Burning, Improvements in and connected with Apparatus for. W. M. Russell, R. E. Lester, and W. M. Ernst, New York, U.S.A. Eng. Pat. 23,391, Dec. 10 1895.

THE specification includes 13 claims, which are for the mechanical details of an arrangement whereby pulverised fuel is reduced to a very fine state of division and fed together with air through a nozzle into the combustion chamber. The chief novelties in the arrangement are in the construction of the pulveriser and the nozzle. The former embraces a casing and a series of rotating bars within it, so arranged as to toss the fuel about and to gradually pass it from the intake to the outlet. The fuel

becomes very finely pulverised during this treatment, and the powder becomes mixed with air drawn into the casing by the motion of the bats. The nozzle is arranged to spread the outgoing fuel into a thin sheet, and is provided with means for increasing and diminishing its outlet, so that the rapidity with which the fuel is fed into the furnace may be varied.—A. G. B.

Pulverulent and Small Fuel Furnaces, Improvements in and relating to. M. Seipp, Berlin, Germany. Eng. Pat. 771, Jan. 11, 1896.

THE air for the combustion of the small coal is drawn by the chimney draught through a screw wheel, such as is frequently used for measuring air, and past a feed roller at the bottom of a hopper containing the fuel. This roller is revolved by suitable gearing from the air-supply wheel, and the small coal contained in the cavities on its surface is blown forward by the air, each cavity being emptied as it is exposed to the blast, and filled when it comes in contact with the fuel. The air and fuel pass through a pipe, a portion of which is set across the furnace in order that a preliminary heating and gasification of the fuel may be effected. The pipe opens into channels in the furnace walls, down which the air and fuel travel, entering the furnace at the bottom. By shaping the furnace like a funnel, the speed of travel of the air and fuel is progressively diminished, so that the heavier particles fall back into the

combustion zone, and do not escape unburnt. By this invention, it is claimed, the air can be supplied at a rate appropriate to the requirement of the fuel, and thus complete and smokeless combustion can be ensured.

—A. G. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Asphalt from Petroleum, Artificial Production of. C. F. Mabery and J. H. Byerley. Amer. Chem. J. 18, 141—150.

By a modification in the final process of distilling the heavier fractions (tar) of petroleum, F. H. Byerley has succeeded in obtaining as residue, various grades of asphalt instead of the coke usually produced. The process consists in introducing a current of air through a number of pipes into the liquid, the decomposing action of the air being minimised by lowering the rate of distillation, which is prolonged to about four or five days. The temperature is first raised to 450° F., and later to 650° F., at which point it is maintained throughout. The distillates are divided into two portions, both of which are refined for burning oils after removal, by steaming, of the sulphur they contain (0.04 to 0.15 per cent.).

The air appears to act mechanically, by preserving the tar from coking on the walls of the still; and chemically, by oxidising sulphur and hydrogen, rather than by forming oxygen compounds in the oil.

Four chief products are formed—liquid asphalt, roofing asphalt, paving asphalt, and "Byerlyte" or varnish asphalt. In percentage composition they differ but little from each other, the carbon content ranging from 86.22 in the first-named to 87.44 in the varnish asphalt. Sulphur is present to the extent of from 0.3 to 0.4 per cent.; hydrogen between 10.90 and 9.30 per cent.; and oxygen from 1.90 to 2.40 per cent.

The varnish asphalt resembles the natural bitumen "Gilsonite," and is suitable for the same industrial purposes. It softens at 230°, and begins to flow at 260° F. In carbon bisulphide it is completely soluble, but less so (62.45 per cent.) in petroleum spirit, 75—110°, and petroleum distillate (59.37 per cent.), 200—250°.

The nature of the decomposition of petroleum distillate, technically known as "cracking," has also received attention at the authors' hands. So far, they have ascertained that the action begins near 250°, but the point varies with oils from different sources, or even from different depths in the same well, considerable fluctuations in the absorption of bromine being exhibited by the various oils examined.

IV.—COLOURING MATTERS AND DYES.

Litmus, Commercial, Note on. D. Riany Brown. Pharm. Journ. 1896, 56, 181.

THERE appears to be little published information concerning the preparation of litmus, but the process is probably somewhat as follows:—Lichens of various species, *Roccella*,

Varioluria, *Lecanora*, are made into a paste with water, and fermented in the presence of ammonia, as in the preparation of archil. When the mixture has a purple tint, stale urine and potassium carbonate are added and fermentation allowed to proceed until the blue colour produced is of the correct tint. It is stated that the best product is obtained in about 40 days. The blue liquor is mixed with chalk, gypsum, or sand, and sometimes alum, to give it consistency. It is then moulded into pieces of the desired dimensions, and more or less thoroughly dried.

The author considers that the addition of chalk, &c., as thickening agents is a doubtful proceeding, and is probably attended with loss of colouring matter from the formation of an insoluble lake; he suggests that it would be advisable to place litmus in the market in the form of a liquid extract, or to acidify the solution, precipitate the colouring matter with excess of alcohol, and offer the product in the dry state.

Indigo is sometimes added during the process of manufacture to improve the colour of the product; it should be regarded as an adulterant, though Wartha suggests that its presence might result from the fermentation of the lichens at the expense of the added urine.

The author estimates the colouring matter—azolitmin—in commercial litmus by exhausting the finely powdered substance with boiling water, evaporating this to a small bulk, and after acidifying with acetic acid, the evaporation is continued nearly to dryness. The object of adding acetic acid is to form potassium and ammonium acetates, which are both soluble in alcohol. A large excess of 85 per cent. alcohol is added to the acidified solution, which precipitates the azolitmin; after standing for 12 hours, the precipitate is collected, and, when dry, is washed through with the smallest quantity of boiling water into alcohol. After standing over-night the precipitate is filtered off, dried, and weighed. In order to check the results the powdered sample was heated on a water-bath with excess of acetic acid, and extracted with warm alcohol; the residue, insoluble in alcohol, was extracted with boiling water, and, after evaporating to a small bulk was precipitated with an excess of alcohol. The precipitate was collected, again exhausted with warm alcohol, dried, and weighed. The products were free from inorganic matter.

Sample.	Per Cent. Moisture.	Per Cent. Insoluble in Boiling Water.	Per Cent. Azolitmin.

—J. L. B.

Sulphonated Colouring Matters derived from Triphenylmethane [Patent Blue]. M. Prud'homme. Bull. Soc. Ind. Mulhouse, 1895, 231—236.

PATENT blue forms an exception to the rule previously advanced by the author (Bull. Soc. Ind. Mulhouse, 1895, 93; this Journal, 1895, 28 and 741), that colourless sulphonated di- and triamidotriphenyl carbinols only become colouring matters when the carbinol hydroxyl is replaced by an acid radicle. The author describes certain reactions of Patent blue, and gives the following formula for the colourless product obtained from the dyestuff by the prolonged action of cold caustic soda (15° B.):—

When this product is acidified with acetic acid and oxidised with lead peroxide it gives tetra-ethylbenzidine, melting at 85° C., together with a green base which dyes silk an unstable grass-green. Similar reactions are given

by the unsulphonated Patent blue base, which in alcoholic solution will dye silk, wool, or tanned cotton. Patent blue does not conform to Rosenstiehl's rule (Bull. Soc. Ind. Mulhouse, 1894, 194; this Journal, 1895, 25) with respect to the position and character of the substituting groups, and whilst the colouring power is due to the presence of the phenolic hydroxyl, it appears that this need not necessarily be attached to the methane carbon, nor even occupy, in one of the benzene rings, a para-position.—T. A. L.

Patent Blue, Constitution of. A. Rosenstiehl. Bull. Soc. Ind. Mulhouse, 1895, 239—242.

The author, replying to Prud'homme (preceding abstract), considers that the hydroxyl group in the meta-position in Patent blue cannot be the cause of the colour, in spite of its acid properties, since it may be replaced by the methoxyl group or by chlorine, without materially altering the characteristic properties of the colour. He is of opinion that the group $C_6H_2[(SO_3)_2Ca]OH$ functions as a negative radicle in opposition to the carbinol hydroxyl, and condenses with it, with elimination of water under the action of acids. This constitution is in accordance with the behaviour of Patent blue and would account for its stability to alkalis, but it must be remembered that the formulæ brought forward are speculative, and have not been experimentally verified.—T. A. L.

Nitrotetramethyldiamidotriphenylmethanes, Reduction of. M. Prud'homme. Bull. Soc. Ind. Mulhouse, 1895, 237—239.

The principal subject-matter of this communication has already been abstracted (Comptes rend. 121, 1895, 891—893; this Journal, 1896, 108). The author now states further, that only the *p*-nitro-derivatives, as might have been expected, give the hydroxylamine reduction, and that this method serves as a test for the position of a nitro-group in di- or triphenylmethanes.—T. A. L.

Colouring Matters of the Rosaniline Series. Ch. Friedel and de Bechi. Sealed communication deposited July 25, 1884; opened Sept. 25, 1895. Bull. Soc. Ind. Mulhouse, 1895, 269—270.

By heating carbon tetrachloride with dimethylaniline and gradually adding aluminium chloride, a bronzy mass is obtained, which dissolves in water with a violet colour. The product is the hydrochloride of hexamethyl-*p*-rosaniline, which was also obtained by Fischer (Ber. 1884, 98) by condensing dimethylaniline with *o*-formic ether $CH(OC_2H_5)_2$. Diethyl- and dibenzylaniline can be condensed with carbon tetrachloride in a similar manner, and the former especially gives a very valuable violet. Hexamethyl-*p*-rosaniline is blue, and insoluble in water. If the carbon tetrachloride be replaced by chloroform, leuco bases of the colouring matters are obtained, which, on oxidation with lead peroxide, give the colouring matters themselves.

—T. A. L.

Triphenylmethane Colouring Matters, Relation between the Colour and Constitution of the. W. Vauel. J. Prakt. Chem. 53, 1896, 47—48.

In the triphenylmethane colouring matters, the group—

is the chromogen, and, for example, the compound—

is an orange colouring matter which, by the introduction of further amido groups into the para position of the other phenyl groups, yields a more or less coloured body, dependent also upon whether these amido groups are acetylated or alkylated. These substituting groups, however, exercise a similar retarding effect when the product is brominated, although the results are not entirely comparable. When a second amido group is introduced into the molecule, an attraction takes place between it and the acid radicle of the chromogen group.

An alkylated amido group is less strongly attracted, whilst an acetylated group is scarcely attracted at all. When, however, the second or third amido group is attached to an acid radicle, there is no longer any attraction, and, as in the case of the acetylated group, no effect is produced upon the colour—as, for example, in the case of magenta, benzaldehyde green, &c., in the form of their secondary and tertiary salts. The ammonium halogen group acts in a similar manner. In these cases also the behaviour on bromination is not a strictly comparable one, since the secondary and tertiary salts can be substituted by bromine. The same is also true of an amido group in the meta position, which has little effect on the character of the colouring matter, but nevertheless the product can still be substituted by bromine.

PATENTS.

Dyestuffs [Azine Reds], The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5796, March 19, 1895.

The colouring matters are obtained by condensing amido-azo-*p*-toluene with phenyl- or tolyl-(1.4)-naphthylamine sulphonic acid in presence of a solvent, such as phenol, alcohol, glacial acetic acid, glycerol, or *p*-toluidine, converting the monosulphonic acids into easily soluble disulphonic acids by suitable sulphonating agents, and finally, alkylating the disulphonic acids by heating the alkaline solution with methyl iodide to 120°—150° C. The following typical example gives the quantities employed:—A mixture of 31.3 kilos. of *p*-tolyl-(1.4)-naphthylamine sulphonic acid and 50—60 kilos. of phenol heated on the water-bath, has gradually added to it 33 kilos. of amido-azo-*p*-toluene, and the whole is heated until a sample dissolves in concentrated sulphuric acid to a pure green solution. Dilute soda lye is then added to remove the phenol, the sodium salt of the monosulphonic acid being simultaneously precipitated. After filtering from the phenol solution, the residue is dissolved in a large quantity of water, the solution filtered, and the *p*-tolyleurhodine sulphonic acid is precipitated with hydrochloric acid. It is purified by boiling with alcohol, in which the pure acid is nearly insoluble, and, after drying, 1 kilo. is stirred into 6 kilos. of sulphuric acid (66° B.) and heated on the water-bath until a sample dissolved in dilute ammonia, is no longer precipitated by acetic acid. The melt is then poured into ice-water, when the disulphonic acid separates. It is purified by dissolving in soda-lye and pouring into brine and caustic soda. The sodium salt produced, separates as a light yellow crystalline mass, which is filter-pressed and dried. In order to alkylate it, 55.5 kilos. of the sodium salt, 14 kilos. of sodium acetate, 150 litres of water, 150 kilos. of methyl alcohol, and 18 kilos. of methyl iodide are heated in an autoclave for three hours to 120°—

130° C. When the action is complete, the alcohol is distilled off and an excess of soda-lye added, when the sodium salt of *p*-tolylmethyleurhodine disulphonic acid separates out. It is purified by repeatedly dissolving it and salting out with salt and soda-lye. The colouring matter produces bluish-red shades on wool, which dye evenly and are fast to light. The corresponding colouring matter from phenyl-(1,4)-naphthylamine sulphonic acid and amido-azo-*p*-toluene gives somewhat yellower shades.—T. A. L.

Colouring Matters [Azine Reds], The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5861, March 20, 1895.

THE process relates to the production of dyestuffs by oxidising a non-alkylated *o*-diamine together with α -naphthylamine or an alkyl derivative thereof, and subsequently sulphonating the product if necessary. A solution of 17.9 kilos. of α -naphthylamine hydrochloride, 15 kilos. of ethyl-*o*-tolylenediamine and 50 kilos. of hydrochloric acid in about 1,500 litres of water, is gradually stirred into 26.3 kilos. of sodium bichromate dissolved in 100 litres of water. The separation of the dyestuff is completed by adding zinc chloride and salt. In order to purify the product, it is repeatedly extracted with boiling water, the united filtrates being made slightly alkaline with ammonia to precipitate an impurity, and, after acidulation with hydrochloric acid, the pure dyestuff is precipitated by zinc chloride and salt. It forms a brick-red-coloured powder, and produces scarlet-red shades on tanned cotton. A dyestuff giving rather yellower shades is obtained by oxidising ethyl-*o*-tolylene diamine and benzyl- α -naphthylamine.—T. A. L.

Dyestuffs [Azine], The Manufacture or Production of, and Materials therefor. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 6176, March 25, 1895.

IN Eng. Pat. 9610 of 1894 (this Journal, 1895, 478) it was shown that by heating salts of *m*-tolylenediamine with primary aromatic amines only the amido group para to the methyl is substituted, the other remaining intact. The resulting compounds are termed alaryl-*m*-tolylenediamines, the term "alaryl" being applied to phenyl, tolyl, and the like, whilst "alkyl" denotes a radicle, such as methyl, ethyl, or benzyl, &c. New alarylamidobenzyl-*o*-toluidines have been obtained by the action of benzyl chloride or bromide on the alaryl-*m*-tolylenediamines, either alone or in solution, and these products yield valuable azine dyestuffs when condensed with nitroso or azo compounds, quinone imides, or the like, or else when oxidised together with *p*-diamines. Similar or analogous colouring matters are also produced by heating primary, secondary, or tertiary aromatic amines of the benzene or naphthalene series with azo compounds obtained by combining diazo compounds with alarylbenzyl-*m*-tolylenediamines, or else by oxidising primary, secondary, or tertiary amines of the benzene or naphthalene series together with the alarylbenzyltriamidotoluenes obtained by reducing the azo compounds above referred to. All these colouring matters may be regarded as benzyl derivatives of the corresponding colouring matters obtained from alaryl-*m*-tolylenediamines. Like these dyestuffs, they are fast to light and alkalis, but are superior to them in brilliancy. The following are two typical examples:—A colouring matter dyeing tanned cotton similar to Rhodamine S is obtained by dissolving 29 kilos. of phenyl-*p*-amidobenzyl-*o*-toluidine in 100 litres of alcohol, gradually adding 29 kilos. of nitrosomethyl-*o*-toluidine hydrochloride and heating until the latter has disappeared. On cooling, the dyestuff crystallises out, and is purified by washing with alcohol. A dyestuff giving bluish-red shades on mordanted cotton is formed by heating together 7.2 kilos. of *p*-sulphobenzene-azophenylbenzyl-*m*-tolylenediamine, 1.4 kilos. of α -naphthylamine, and 20 kilos. of phenol at 90°–110° C., until the melt is a pure red. Warm dilute soda-lye is then added in excess, and, after cooling, the dyestuff is pressed off. The press cakes are dissolved in hot water containing hydrochloric acid, and, after filtering, hydrochloric acid is added to the solution.

On cooling, the colouring matter which crystallises out is filter-pressed and dried.—T. A. L.

Substituted Fluoresceins, Manufacture of Dyestuffs from. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brünig," Hoechst a M., Germany. Eng. Pat. 7170, April 8, 1895.

WHEN tetrabromfluorescein is strongly heated with concentrated sulphuric acid, it yields, as already pointed out by Bayer (Annalen, 183), a bromocerulein. The yield, however, is small, but may be increased, as the patentees have discovered, by the use of fuming sulphuric acid according to the following method:—A mixture of 1 kilo. of eosine and 5 kilos. of fuming sulphuric acid containing 20 per cent. of anhydride is heated for three-quarters of an hour to 125–130° C., after which, sufficient water or ice having been added to convert the anhydride into sulphuric acid, the melt is again heated to 150° C. for 2–3 hours. After this time it is poured into water and either used as a paste or converted into the sodium salt, when it can be salted out, filter-pressed, and dried. The colouring matter dyes chromed wool a bluish-green, and it also dissolves in an alkaline alcoholic solution with this colour, which is fast to light.—T. A. L.

Azo Colouring Matters, Manufacture of, Dyeing Unmordanted Cotton in Acid, Neutral, or Alkaline Bath. J. Imray, London. From "La Société Anonyme des Matières Colorantes et Produits Chimiques de St. Denis" and D. A. Rosenstiel, Paris, France. Eng. Pat. 7237, April 9, 1895.

THE colouring matters are obtained from azoxyamines by conversion into tetrazo compounds and subsequent combination with naphthalene derivatives, such as amidonaphthol sulphonic acid G, acid H, dihydroxynaphthalene sulphonic acid S or chromotrope acid. A modification of the method consists in diazotising the corresponding oitramine, combining it with a naphthalene derivative, and reducing the product, which dyes wool but not cotton, with an alkaline reducing agent, such as glucose, arsenious acid, or sodium sulphide. The dyestuff obtained is identical with that obtained according to the first-described method. A solution of 11.4 kilos. of *p*-azoxyaniline, melting at 187°–189° C. in 100 litres of boiling water and 25 kilos. of hydrochloric acid (20° B.), is diluted to 600 litres with water and ice, and diazotised with 7 kilos. of sodium nitrite in 21 litres of water. The tetrazo solution produced is then run into 150 litres of water, containing 23.9 kilos. of amidonaphthol sulphonic acid G and 21 kilos. of sodium carbonate, and cooled with ice. A black colouring matter can be separated by adding 15 kilos. of salt. The same product is also obtained as follows:—The diazo solution from 13.8 kilos. of *p*-nitraniline is combined with 23.9 kilos. of amidonaphthol sulphonic acid G, dissolved in 150 litres of water with 21 kilos. of sodium carbonate. The resulting colouring matter dyes wool brown, but will not dye cotton. In order to convert it into a cotton-colouring matter, the solution, after the combination is complete as above, has added to it 100 litres of caustic soda-lye of 40° B. and 13 kilos. of glucose dissolved in 100 litres of water, the whole being then heated to 40° C. for four hours with constant agitation. When the reduction is complete the colouring matter is salted out. The products obtained from the *p*-azoxyamines give violet, blue, and black shades, whilst the *m*-azoxyamines give browns; thus *m*-azoxy-*o*-toluidine, after combination with amidonaphthol sulphonic acid G, gives a brownish-red colouring matter, dyeing unmordanted cotton from an acid, neutral, or alkaline bath.

—T. A. L.

New Substantive Dyestuffs, Manufacture of [Cotton Blues]. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brünig," Hoechst a M., Germany. Eng. Pat. 7549, April 13, 1895.

THIS is an extension of Eng. Pat. 14,134 of 1894 (this Journal, 1895, 650), and has reference to the production of dyestuffs from the 1,4,3'- and 1,4,2'-naphthol disulphonic acids. The improvement consists in combining equimolecular proportions of one of these acids and tetrazotised

benzidine, tolidine, dianisidine, diphenetidine, &c., and coupling the intermediate compound so formed with one molecular proportion of a phenol, an amine, or their sulphonic acids. The diazo solution from 12.2 kilos. of dianisidine is run into a solution of 18 kilos. of 1.1.2'-naphthol sodium disulphonate. After 12 hours, 12.5 kilos. of sodium amidonaphthol sulphonic acid G are added, the mixture is stirred for some hours, then heated and the dyestuff salted out. It dyes un mordanted cotton a blackish-blue, and can be diazotised on the fibre and developed with *m*-phenylene- or *m*-tolylenediamine. By substituting acid H for the acid G, a pure greenish-blue dyestuff is obtained.—T. A. L.

Colouring Matters. The Manufacture of [Safranines]. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 7665, April 16, 1895.

It has been already shown that the oxidation of an alkylated *o*-toluidine together with a primary aromatic amine and a *p*-diamine containing at least one unsubstituted amido group, gives rise to new safranin colouring matters. According to the present invention, the same dyestuffs are obtained by alkylating safranines derived from *o*-toluidine, the following being a typical example:—A mixture of 36 kilos. of tolusafranine (by oxidising one molecular proportion of *p*-amido-*o*-toluidine and two molecular proportions of *o*-toluidine), 100 kilos. of alcohol, and 22 kilos. of ethyl bromide is heated for 10 hours to 180° C. The alcohol having been distilled off, the residue is dissolved in water and the alkylated tolusafranine salted out. It dyes tanned cotton similar shades to that given by the dyestuff obtained by oxidising equimolecular proportions of *p*-amido-ethyl-*o*-toluidine, ethyl-*o*-toluidine, and *o*-toluidine.—T. A. L.

Direct-dyeing Colouring Matters, Manufacture of [Blue-Blacks]. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 7969, April 22, 1895.

This is an extension of Eng. Pat. 4018 of 1895 (this Journal, 1896, 110), the patentees showing that the process referred to in the previous patent may be applied to a series of tetrazo compounds having the following general formula:—

in which X and Y signify amido or hydroxyl groups. The following example illustrates the method employed:—The tetrazo compound, prepared in the usual way from 11 kilos. of the product having the formula—

is slowly added to an alkaline solution of 6.1 kilos. of *m*-tolylenediamine. The colouring matter, which separates as a dark precipitate, is filtered off and dried. It dissolves to a dark violet solution in water, and dyes un mordanted cotton from a salt or soap bath a deep black. A similar dyestuff can be obtained by combining the tetrazo compound from 14 kilos. of the product—

and 3.5 kilos. of sodium nitrite, with the same quantity of tolylenediamine.—T. A. L.

Dis- and Polyazo Dyestuffs [Cotton Blacks] from γ -Amidonaphthol sulphonic Acid, Producing. S. Pitt, Sutton. From L. Cassella and Co., Frankfurt a. M., Germany. Eng. Pat. 8572, April 30, 1895.

This invention relates to new combinations of colouring matters from γ -amidonaphthol sulphonic acid, several of which have already been described in Eng. Pat. 16,699 of 1889, 19,330 of 1890, 9529 of 1894, and 25,018 of 1894 (this Journal, 1890, 935; 1891, 917; 1895, 478 and 1041). In addition to the components mentioned in the two last specifications it has been found that the following give valuable products: the dihydroxynaphthalene sulphonic acids and those mono-azo dyestuffs from the peri-amidonaphthol sulphonic acids which are formed in acid solution and still react with diazo compounds in alkaline solution.

The tetrazo compound from 21.2 kilos. of tolidine is combined in an alkaline solution with 24 kilos. of γ -amidonaphthol sulphonic acid, and the intermediate compound, after rediazotisation, is added to a solution of 32 kilos. of 1.1'.3.3'-dihydroxynaphthalene disulphonic acid kept alkaline. The formation of the second intermediate compound is complete in a short time, when 10.8 kilos. of *m*-phenylenediamine are added and the mixture is heated to 40° C. The dyestuff is finally salted out and dyes un mordanted cotton black. The following method is another modification of the process:—27 kilos. of *p*-amido-benzene-azo-amidocresol ether are diazotised by means of 60 kilos. of hydrochloric acid and 14 kilos. of sodium nitrite. When the solution is no longer turned bluish-black but greyish-brown by soda, the formation of the tetrazo compound is complete, and it is then rapidly mixed at 0° C. with 24 kilos. of γ -amidonaphthol sulphonic acid and 60 kilos. of sodium carbonate, 11 kilos. of *m*-phenylenediamine being added immediately afterwards. After about 12 hours, the mixture is heated to 60°–70° C. and the dyestuff is salted out. It gives bluish-black shades on un mordanted cotton.—T. A. L.

New Sulphonic Acids derived from Naphtholine and of Colouring Matters [Red, Violet, and Blue] therefrom, Improvements in the Production of. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 8645, May 1, 1895.

THE 2.3.3'-amidonaphthol sulphonic acid of Eng. Pat. 15,176 of 1889 (this Journal, 1890, 855) can be converted into the following new acids:—2.3.3'.1'-amidonaphthol disulphonic acid, 2.3.3'.1'-naphthylenediamine disulphonic acid, 2.3.1'.3'-diamidonaphthol sulphonic acid, and 2.3-azimido-1'.3'-naphthol sulphonic acid. (1.) A solution of 10 kilos. of 2.3.3'-amidonaphthol sulphonic acid in 30 kilos. of fuming sulphuric acid (25 per cent. SO₃) is heated on the water-bath until a sample no longer gives a yellow precipitate on the addition of sodium nitrite. The melt is then poured into water and the lime or sodium salt prepared in the usual manner. The acid yields an easily soluble diazo compound, which gives a red solution with an excess of soda. When combined with tetrazodiphenyl it forms a violet-red and with diazobenzene a brownish-red dyestuff. (2.) On heating 100 kilos. of the 2.3.3'-amidonaphthol sulphonic acid and 200 kilos. of 30 per cent. ammonia liquor to 185°–190° C. for eight hours, 2.3.3'.1'-naphthylenediamine disulphonic acid is formed, which can be separated by boiling off the excess of ammonia and acidulating the melt with hydrochloric acid. This acid only combines with one molecular proportion of sodium nitrite, being converted into an azimide, but the new product will combine with diazo compounds to form azo colouring matters. (3.) The action of caustic soda on 2.3.3'.1'-naphthylenediamine disulphonic acid at 190°–200° C. causes the substitution of the hydroxyl group for a sulphonic acid group, the resulting compound being 2.3.1'.3'-diamidonaphthol sulphonic acid. (4.) When the foregoing acid is treated with sodium nitrite in an acid solution, an azimido compound is obtained. All these new acids are capable of combining with diazo and tetrazo compounds, the former yielding wool and the latter un mordanted cotton dyestuffs, all of which give deep shades and are fast to washing and light. The shades vary, according to the components employed, from yellowish-red to dark violet-blue.—T. A. L.

Polyazo Colouring Matters [Cotton Blacks], Manufacture of. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 9431, May 13, 1895.

THESE colouring matters are derivatives of diazo compounds having the following typical constitution:—

in which X and Y represent amido or hydroxyl groups, whilst R is the radicle of an aromatic diazo compound not containing a diazotisable amido group. These compounds may be obtained by reacting on an amidonaphthol, dihydroxynaphthalene, or naphthylenediamine sulphonic acid

with one molecular proportion of an aromatic diazo compound and one molecular proportion of *p*-nitrodiarobenzene and subsequent reduction by means of alkaline sulphides. For instance, 32 kilos. of the combination product from acid H, amidoarobenzene and *p*-nitraniline having the following formula:—

is diazotised with 3.5 kilos. of sodium nitrite and the dark blue solution of the diazo compound is run into a solution of 5.5 kilos. of *m*-tolylenediamine kept alkaline by sodium carbonate. After agitation for some time, the whole is heated on the water-bath and the colouring matter filtered, pressed and dried. It is easily soluble in water, and dyes unmordanted cotton black. By substituting the equivalent quantity of β -naphthol for the tolylenediamine, a colouring matter dyeing blue-black shades is produced.—T. A. L.

Nitrated Orazine Colouring Matters [Bright Greens and Greenish-Blues] Dyeing with Mordants, Manufacture of. C. D. Abel, London. From L. Durand Huguenin and Co., Basle, Switzerland. Eng. Pat. 24,842, Dec. 27, 1895.

THE blue colouring matter of Eng. Pat. 583 of 1891 (this Journal, 1891, 359), obtained by the action of aniline on the condensation product of nitrosodimethylaniline hydrochloride and tannin-anilide, and subsequent sulphonation, can, according to the present specification, be re-nitrated, yielding green mordant colouring matters. The following method is employed for the nitration:—20 kilos. of the condensation product, after having been converted into the anilide, are gradually stirred into 100 kilos. of a 92 per cent. sulphuric acid. The melt is then raised to 80°—85° C., until a sample dissolves in dilute alkali. After cooling to 0° C., 2·4 kilos. of nitric acid (86·6 per cent.) and 6 kilos. of sulphuric acid (96 per cent.) are added below 10° C., and in about 10—12 hours the melt is poured into water, which precipitates the new nitro acid. This, after conversion into the ammonium salt, is soluble in water with a bluish-green colour, whilst the solution in concentrated sulphuric acid is crimson-red. Other nitrated oxazines are obtained by the action of 1.2.4-chlorodinitrobenzene or picryl chloride on the condensation product of nitrosodialkylated aniline hydrochloride or dialkylated amido-azobenzene hydrochloride with gallamic acid. 21 kilos. of the condensation product in 1 litre of water, 2 litres of alcohol, and 5·3 kilos. of sodium carbonate are mixed with 10 kilos. of chlorodinitrobenzene. After heating on the water-bath for three hours the new product separates as a crystalline mass, having the following formula—

This product, unlike the oxazine of Eng. Pat. 11,848 of 1889 (this Journal, 1890, 610), cannot be sulphonated, but it can be converted into a bisulphite compound by heating 5 kilos. of it with 20 kilos. of alcohol and 20 kilos. of a 40 per cent. bisulphite solution on the water-bath for some time, when the bisulphite compound separates as a shining green mass, which dyes mordanted cotton violet to blue shades. The dinitro derivative can also be converted into an anilide by heating it with twice its weight of aniline on the water-bath for half an hour. This product can be sulphonated, and the resulting sulphonic acid, after conversion into the ammonium or sodium salt, dyes chromed wool bright green, whilst unmordanted wool is dyed a greenish-blue. Similar results are obtained with picryl chloride.

—T, A, L,

Colouring Matters, Dyeing Wool Green-Black to Blue-Black, Manufacture of. O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 698, Jan. 10, 1896.

THE unsymmetrical diazo colouring matters of Eng. Pat. 15,457 of 1895 (this Journal, 1895, 1042), which dye animal

fibre violet-black to blue-black, can, when heated together with certain condensing agents, be converted into colouring matters dyeing bluer or greener shades. The transformation is carried out in an aqueous solution in open or closed vessels, preferably by the action of zinc chloride on the colouring-matter acid, or if this be a salt, then the condensation may be effected by means of a mineral acid or an organic acid, such as oxalic, acetic, benzoic, phthalic acid, &c. It is of course unnecessary to isolate the colouring matter obtained according to the former patent, and the two processes may be combined. The following example illustrates the method employed:—5 kilos. of the colouring matter obtained by the successive combination of 1, 1', 3', 3'-naphthylenediamine disulphonic acid with diazobenzene and *p*-nitrodiazobenzene dissolved in 100 litres of water, is mixed with 5 kilos. of acetic acid, and the whole is heated on the water-bath for 8 hours, or until the desired shade has been obtained. After neutralisation with sodium carbonate, the new colouring matter is salted out, filtered-pressed, and dried. It dissolves in water with a bluish-green colour and dyes wool greenish-black from an acid bath.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Textile Fabric from Glass and Silk. V. Schlumberger.
Bull. Soc. Ind. Mulhouse, 1895, 267—268.

THE article contains a description of a material composed of alternate wefts of silk and glass on a silk warp. The glass is spun at the rate of 1,500 metres a minute from a rod heated in a blow-pipe to 1,200° C., and wound on to a fly-wheel rotating at 400 revolutions per minute. When this is full the fibre is wound directly on to the shuttle spindle, or else for certain purposes cut into equal lengths. The material is woven on a Jacquard hand loom, the warp being of silk or cotton and the weft alternately glass and silk. Very pleasing effects are produced, but as the price of the material is very high (100 francs per metre), its application is limited.

—T. A. L.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Blood Albumin, Decolorisation of. J. Persoz. Sealed communication deposited June 12, 1885; opened Sept. 25, 1895. Bull. Soc. Ind. Mulhouse, 1895, 271—272.

WHEN ox-blood serum is treated with one-fifth its volume of hydrogen peroxide (12 vols.) in a 'very faintly acid solution,' it is gradually decolorised, and after 24 hours' standing has an appearance similar to egg albumin. The liquid is odorless and will keep for some time in contact with the air without alteration. It coagulates to a perfectly white mass and at a lower temperature than serum diluted to the same volume with ordinary water, more especially when exposed to direct sunlight. The concentration of the liquid is of importance, and decolorisation takes place more rapidly in serum acidulated with acetic acid; moreover, the coagulating point can be considerably lowered. Presence of ammonia, on the other hand, retards the action; the liquor remains brownish and is malodorous. The hydrogen peroxide employed contained small quantities of hydrochloric and much sulphuric acid, so that it was necessary to nearly neutralise with ammonia and subsequently add ammonium acetate in order that the acidity should be due to acetic acid only. The author suggests that the excess of sulphuric acid should be removed by baryta in order not to introduce any large quantity of ammonium sulphate into the serum.—T. A. L.

Colours on Wool, Fastness to Light and to Street-Mud.
G. Dommergue. Rev. de Chim. Ind. 1896, **7**, 39—40.

Fastness to Light.—Determined by exposing the dyed patterns for periods of one, two, and three months respectively. The following observations are recorded:—

The blue least affected by light, is Prussian blue. Indigo-extract blue fades regularly, and is completely destroyed after three months' exposure. Composite blues (mixtures of Methyl and Acid greens and violets, employed in France under the name of *Indigo substitutes*) fade into dull greys.

The Alkali and Nicholson blues in full shades are fast, as are also blacks (presumably from logwood), on the chromium mordant.

The *green* from Indigo and Pierie acid is changed into a dull grey after three months' exposure.

Old Fastie *yellow* completely disappears in three months.

Acid Magenta, Orchil, and the Methyl violets are also destroyed.

The following colouring matters are moderately fast:—Quinoline yellow, Flavamine S (M.L.B.); Indian yellow (Monnet); Naphthol yellow (B.A.S.F.); Erythrin (B.A.S.F.) (these become slightly darker on exposure); Pierie acid (becomes darker and orange).

Naphthol yellow S (B.A.S.F.), Orange Q (Poirier), Crocein orange (Bayer), Amaranth and Bordeaux R and B (M.L.B.), the Xylidine ponceaux, Crocein scarlets, and Cochineal scarlet are fast.

Fastness to Street-Mud.—The mud of the streets has an alkaline reaction.

The following colouring matters are not affected by it:—

(*Reds*) Brasilen (Brazilwood), Amaranth, Bordeaux B and R, the Ponceaux, Roccellin, Erythrin (presumably the azo dyestuff of this name), and Crocein orange; (*blues*) Indigo, Alizarin blue, Induline, and Blue-black (the two last are not fast to rubbing); (*yellows*) Naphthol yellow S, Indian yellow, and the orange azo-colouring matters.—E. B.

Moleskin, Half-Moleskin, and Buckskin, Printed, Manufacture of. B Maslowski. *Färber Zeit.* 1896, 7, 97–98.

UNDER the above names a kind of dyed and printed material is manufactured for garments in Russia. The raw goods are passed under an emery wheel on both sides to remove irregularities, and shaved, either on one or both sides, according to the manner in which they are to be printed. They are next "boiled" in one of three ways:—(1.) The pieces are packed in a keir, and boiled with water for from 6 to 8 hours at 1 atm. pressure, after which they are sewa together, spread out, and washed first with warm water and then with cold. Finally they are pressed and dried. (2.) The pieces are drawn flat through warm water, pressed, and laid away in packs in vats, where they are covered with warm water and weighted with loaded boards; they remain in these vats for three days, during which time the water must be kept at 30–35° C., and must cover the goods. The thick moleskins are then washed with warm water in a jigger, and the lighter goods are passed through warm water several times and then through cold water. As before, pressing and drying are the final processes. (3.) The goods are sent through two or three tumblers containing warm water in which some soda (200 grms. per piece of 70 metres) is dissolved, and are there left rolled up for 24 hours. They are then handled in warm water containing soda, and are spread out and washed and dried.

After this boiling process the goods are ready for printing, a variety of recipes for which is given.—A. G. B.

Calf-Leather Dyeing. F. Kast. *Färber Zeit.* 1896, 7, 98–100.

CALF is among leathers what silk is among textile fibres, for it is readily dyed of all shades. There are, however, certain difficulties which many manufacturers never overcome, and important amongst these are those which arise from improper preparation of the leather. In small works the preliminary softening is effected by a short soaking in sufficient lukewarm water to cover the leather, followed by an hour's pounding with oak stamps; water at 40° C. is then run into the vat, and the goods are thoroughly handled for some time; the turbid water is drained off, and the stamping and handling repeated until the right degree of slipperiness has been attained. Tumblers replace the stamps in larger works. After the softening process the leathers are made up into pairs, one leather being stretched grain downwards on a glass or zinc table, and another stretched on the top of this one with the grain upwards; this affords an opportunity for striking out certain blemishes, and is also conducive to economy of dyestuff, since the flesh sides are not exposed in the dye-bath.

The water for the dye-bath should be acidified with acetic acid to avoid the hardening effect of calcareous matters on

the leather. For light shades, alum or bichromate of potash are the mordants; for medium tones, a purer acetate of iron is used; whilst pyrolignite of iron (about 15° B.), nitrate of iron (30° B.), or sulphate of iron (30° B.) serve for the darker shades. Alum is but little used. Bichromate of potash is applied to the extent of 10–20 grms. per pair of leathers, the whole being generally added at once; the leather is well handled in the bath for 10 minutes, and transferred to a fresh bath, to which a small portion of the dyestuff has been added; into a second fresh bath the remainder of the dyestuff is introduced, and the dyeing is completed therein. If a smaller proportion of bichromate is being used, the dyeing can be completed in the first bath. When iron mordants are used, acetic acid must be present in the mordant bath, and it is advantageous to use the feeblest iron salts for grounding. A dilute iron mordant (the purer acetate at 2° B. or pyrolignite at about 10° B.) saddens gradually, whilst a stronger liquor is very active and "goes quickly on," so that uneven dyeing easily results. Cold-washing after the iron mordant is to be avoided, since the leather is thereby hardened. The foregoing mordants are for basic dyestuffs, acid dyestuffs not being amenable to such treatment.

The following list of leather dyes is given:—

Basic.	Acid.
Auramine.	Quinoline yellow.
Phosphine N.	Naphthol yellow.
Phila-lephia yellow.	Carbureum.
Leather yellow.	India yellow.
Aniline yellow.	Azo acid yellow.
Phosphine P.H.	Orange II.
New phosphine.	Mandarin G extra.
Phosphine superfl.	Ponceau BO extra.
Thioflavine T.	Ponceau 3 R B.
Xanthine.	Scarlet for leather.
Camelle.	Ponceau B extra.
Leather red.	Pure blue.
Grenadine.	China blue.
Camelia B.	Bavarian blue.
Russia-leather red.	Fast blue for leather.
Bismarck brown.	Acid green.
Manchester brown P.S.	Guinea green.
Vesuvine.	Fast brown O.
Cachou brown D.	Fast brown 3 B.
Leather brown A and B.	Eosin.
Malachite green.	Erythrosin.
Diamond green.	Phloxin.
Methylene blue.	Rhodamine.
Methylene dark blue B.R.N.	Nigrosin.
Coal black.	
Leather black.	
Leather black 452.

PATENTS.

"Kaki" Dye. An Improved. J. Puxbury, Manchester. From E. A. Mitchell, Madras, India. Eng. Pat. 7498, April 13, 1895.

THE following recipe is given for obtaining a kaki dye of an average shade for cotton or woollen goods. About 2 lb. of myrabolans or divi-divi, 2 oz. of sulphate of zinc or copper, 1, 2, or more oz. of tanning bark, catechu and redwood, and 10–30 or more grains of ferrous sulphate, according to the shade required, are mixed with 6 galls. of boiling water and soaked for two hours. Subsequently a solution of 6 oz. of potassium bichromate in 6 galls. of boiling water is added to render the dye fast. The shade depends upon the proportion of metallic sulphates present, and copper sulphate alone may be used for the lighter, whilst ferrous sulphate produces the darker shades.

—T. A. L.

Dyeing Apparatus, Improvements in. E. E. Middleton, F. P. Middleton, and A. T. Middleton, Adlington. Eng. Pat. 2860, Feb. 9, 1895.

IMPROVEMENTS in Obermeier's apparatus for dyeing eops under hydraulic pressure are here introduced. Instead of the cases being open at the ends and sides, they are formed closed, leaving only two sides open. Planed frames are fixed upon the edges of the open sides, and these fit into slides in the vat. By means of a thin strip of india-rubber

attached to the frame or the slide, a perfect joint is obtained, so that on pumping in the dye-liquor through the case containing the cops, none of this liquor can pass out of the vat, except through the cops.—J. J. K.

Washing and Dyeing Machinery for Piece Goods, Improvements in or in connection with. J. Hudson and H. P. Richardson, Leeds. Eng. Pat. 7058, April 6, 1895.

An invention for automatically stopping a machine in which the fabric passes between squeezing rollers in case the piece becomes doubled or folded between the rollers.

—R. B. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Metals; Nitrides of the, Direct Production of, from Atmospheric Nitrogen, and the Formation of Ammonia. A. Rossel and L. Frauck. Chem. Zeit. 1896, 20, 38.

RICKMAN, in 1878, produced small quantities of ammonia by the action of air on an incandescent mixture of carbon and potash (Ber. 1879, 12, 2389). Briegleb and Genther (Ann. Chem. Pharm. 123, 228) showed that pure nitrogen, acting on magnesium at a red heat, formed Mg_3N_2 ; Mallet (Jahresber. Chem. 1878, 241) proved that prolonged ignition of magnesium in air yielded a nitride as well as an oxide; and Winkler (Ber. 1890, 23, 121a) found that the admixture of an indifferent substance with magnesium, by hindering oxidation, favoured the formation of nitride. It is now observed that when finely-divided calcium carbide is heated with magnesium powder in an open crucible, at a low red heat, the calcium compound forms lime and carbon dioxide with the oxygen of the air, and nearly the whole of the magnesium is found, on cooling in air, to be converted into the nitride. The magnesium nitride is acted upon by water according to the equation—

Aluminium, zinc, and iron also take up nitrogen from the air under similar conditions.—W. G. M.

Barium and Calcium Ferrocyanides, Use of Organic Bases in Preparation of. P. H. Walker. J. Amer. Chem. Soc. 1895, 17, 927–931.

The author prepares these salts through the medium of organic bases in the following manner:—

Strychnine is converted into the acetate and the calculated quantity of potassium ferrocyanide added to the solution. The mixture is kept in a warm place, stirred frequently, and the white crystalline strychnine ferrocyanide which separates, is filtered and washed, and decomposed with excess of ammonia, whereby ammonium ferrocyanide is formed and strychnine precipitated, which latter can be used over again. The solution of ammonium ferrocyanide is boiled with the calculated quantity of barium hydroxide until free of ammonia. The solution, on cooling, deposits crystalline barium ferrocyanide.

It was found that the most favourable results were obtained by the use of dimethylaniline. A solution of dimethylaniline hydrochloride was treated with potassium ferrocyanide, and the precipitate washed with the least possible amount of water, then with alcohol, finally with ether. Dimethylaniline ferrocyanide—

so prepared is a white crystalline substance somewhat soluble in water. This salt is then mixed with a solution of barium hydroxide and vigorously shaken. The barium ferrocyanide immediately crystallises out and can be filtered from the liquid, the dimethylaniline being recovered by shaking the filtrate with ether, which simultaneously brings about the separation of more ferrocyanide.

Calcium ferrocyanide may be prepared by shaking dimethylaniline ferrocyanide with milk of lime, allowing the mixture to stand for some time, and then shaking with ether. The ethereal solution of dimethylaniline is separated and the solution containing the ferrocyanide

evaporated to a small bulk in a flask, carbon dioxide passed through, again boiled, filtered, and evaporated to a small volume. Alcohol is then added, which causes the separation of pale yellow crystals of calcium ferrocyanide.

The author appends the following note:—

Since strychnine ferrocyanide is almost insoluble in water, and is easily filtered, it may possibly be used for the separation of iron and aluminium.

The solution containing ferric and aluminium salts is treated with excess of strychnine ferrocyanide. The Prussian blue thus formed can be filtered, and the aluminium present in the filtrate precipitated with ammonia.—J. L. B.

Sulphuric Acid Manufacture, Recent Improvements in. F. J. Falding. Eng. and Mining J. 1896, 61, 257.

The charge for burners, in a large number of acid systems, has without any structural changes whatever been raised from 750–800 lb. of 50 per cent. pyrites, to 1,150–1,200 lb., an increase of about 50 per cent.; or from 850 lb. of 40 per cent. ore to 1,300–1,400 lb., an increased capacity of about 60 per cent. of ore burned, or about 50 per cent. of actual sulphur burned. Similar results have been obtained with brimstone as the raw material. The only change mentioned is increased circulation of gases, &c., by the use of fans.

The chamber process has been improved, and in the United States the average throughout the year at a number of works is 12 cu. ft. of chamber space to each pound of sulphur burned. This is an average increase of working capacity of 50–80 per cent.

By combining improvements in the capacity of both burners and chambers, an increase of about 50 per cent. on the ordinary output is obtainable.

The author suggests that the proper use of fans would render possible the economical use of the various tower condensers which have been proposed. —A. S.

PATENTS.

Cyanides, Manufacture or Production of, Improvements in Means to be employed in the. J. W. Swan, Bromley, and J. A. Kendall, Streatham. Eng. Pat. 3509, Feb. 18, 1895.

To obtain potassium cyanide, a mixture of charcoal and tungsten, or charcoal that has been soaked in solution of potassium tungstate and then dried, is placed in a cylinder of nickel, cobalt, or fine iron, enclosed within an earthenware jacket, set on a slight incline in a furnace, and strongly heated. The cylinder has at the end opposite to the charging end, a continuation pipe of platinum, entering a case or receiver. Potassium carbonate is fused in a platinum vessel, and run into a funnel tube entering the front part of the cylinder in a controlled stream. Hydrogen gas is passed continuously into and through the space between the cylinder and its jacket, in order to protect the former from corrosion. Nitrogen or ammoniacal gas is passed through the inner vessel. The cyanide, as it forms, distils into the receiver; but the residue in the cylinder at the end of the operation may be lixiviated to recover any cyanide present. Tungsten may be replaced in the described mixture by titanium, molybdenum, chromium, manganese, uranium, or their compounds.—E. S.

Acetates, Improvements in Purifying. A. R. Scott and T. Henderson, Glasgow. Eng. Pat. 6711, April 2, 1895.

SOLUTION of impure sodium acetate (for instance) is boiled with addition of sodium hypochlorite until the colour is nearly discharged. After cooling and settling, the solution is decanted from the sediment, to obtain crystals of the acetate of great purity.—E. S.

Chlorine, Improvements in the Manufacture of, and in the Treatment of By-Products of the said Manufacture. J. Raschen and J. Brock, Liverpool. Eng. Pat. 7287, April 9, 1895.

THREE equivalents of sodium chloride are mixed with one equivalent of sodium nitrate, and an excess of sulphuric acid is added to the mixture, heat being applied to complete the reaction. The gases evolved, nitrosyl chloride, chlorine, and hydrochloric acid, are passed through strong sulphuric acid. Chlorine and hydrochloric acid escape, and are separated by passage through water, the chlorine being collected for utilisation in the manufacture of bleaching powder or otherwise. The nitroso sulphuric acid formed by the action of the sulphuric acid upon the nitrosyl chloride, is treated with sodium chloride, when nitro-yl chloride and hydrochloric acid are given off. Hydrogen preferably, or water-gas, is added to the gaseous mixture, which is then passed over platinised asbestos, heated in a tube or vessel through which an inert gas has been sent to displace oxygen. The ammonia, hydrochloric acid, and aqueous vapour produced, are conducted into a chamber maintained at about 100° C., wherein ammonium chloride condenses. The moist hydrochloric acid may be condensed in a coke tower, and may be mixed with nitric acid to produce nitrosyl chloride for re-use as described.—E. S.

Ammonia and its Salts, Manufacture of, from Nitrogen Oxichlorides or Nitrogen Oxides. Improvements in the. J. Raschen and J. Brock, Liverpool. Eng. Pat. 7288, April 9, 1895.

A MIXTURE of nitrosyl chloride and hydrogen, the latter in slight excess over the proportion required by the equation $\text{NOCl} + 6\text{H} = \text{NH}_4\text{Cl} + \text{H}_2\text{O}$, is passed over heated platinised asbestos, all atmospheric oxygen having been previously displaced from this platinised asbestos and from its containing tube or vessel, by an inert gas, such as nitrogen or carbonic acid. The mixture of ammonia, hydrochloric acid, and aqueous vapour produced is passed into a chamber kept at about 100° C., in which ammonium chloride is deposited. The hydrogen required is preferably obtained by passing steam over incandescent coke. Nitrosyl chloride may be replaced in the process by nitrogen oxides, free ammonia and aqueous vapour being produced. The ammonia may be condensed, or transformed into any required ammonium salt.—E. S.

Carbon Dioxide, Methods of Solidifying, and of Utilising the Solidified Substance, Improvements in. H. S. Elworthy, Bandra, Bombay, and P. D. Henderson, London. Eng. Pat. 7436, April 11, 1895.

CARBONIC acid gas is liquefied, and passed through a coil contained in a "regenerative-refrigerating" apparatus, the coil being placed within an upright closed cylinder within an external cylinder, the space between being exhausted of air, to form a vacuum, non-conductive of heat. From the coil the liquid passes to a combined motor-pump, which it drives, and thence is sent through a pipe, the open end of which enters the upper part of a solidifying chamber, shaped like a covered inverted funnel, jacketed, and with vacuum space between. Here the liquid jet sprays out and solidifies as snow, which falls into a box at the bottom in which the carbonic acid snow is compressed into a block by the ram of a hydraulic press. As gas accumulates in the solidifying chamber, it passes by a suitably arranged tube to the cylinder containing the refrigerating coil. Modified forms of apparatus are shown and described to which the same essential features pertain, especially the system of vacuum-jacketing. In one of these a jacketed close tank containing alcohol has, arranged in it, a series of boxes surrounded by a coil, into which coil liquid carbonic acid is run, and in which it volatilises, thus greatly cooling the alcohol bath, and also the boxes. Part of the expanded gas enters the boxes, forming snow, and part is passed through the cylinder of a motor, to be returned to the boxes, where it consolidates into "ice," and may be removed in that state.

The solidified carbonic acid may be compressed into blocks or slabs, for convenience of application in aerated waters, wines, and the like. It is stated that the solidified

gas may be stored or transported in felt bags or in ordinary ice-boxes. But preferably, a special ice-box is made with double or triple walls, of metal or glass, secured air-tight, and with the intervening space rendered vacuum, as by Prof. Dewar's method.—E. S.

Soda, Bicarbonate, Manufacture of, Improvements in. J. Brock and J. Hawliczek, Liverpool. Eng. Pat. 8314, April 26, 1895.

Coke or sodium bicarbonate or sesquicarbonate, such as the "roaster ash" of the ammonia-soda process, is treated with steam in a close vessel, the mass being well agitated; after sufficient hydration, carbonic acid gas is passed in, with continued agitation. The salt is thus completely converted into bicarbonate, and may be dried while yet hot with a stream of carbonic acid gas. As an alternative process, the roaster ash may be subjected to the joint action of steam and carbonic acid gas.—E. S.

Gas Liquor, or like Ammoniacal Liquor, Improvements in the Treatment of, and in Obtaining Useful Products therefrom. H. Bower, Philadelphia, U.S.A. Eng. Pat. 8330, April 26, 1895.

GAS LIQUOR is distilled, after addition of iron or an iron salt and of lime, to remove ammonia, the cyanogen present being left in the liquor as calcium ferrocyanide and sulphocyanide. So far the process is similar to that described in Eng. Pat. 2918 of 1882. An acid solution of a copper salt, preferably cuprous chloride, is added to obtain a mixed precipitate of copper ferrocyanide and sulphocyanide, which is separated. The moist precipitate is agitated with finely divided iron, to produce copper and iron ferrocyanide and soluble iron sulphocyanide. The iron ferrocyanide, on treatment with an alkali, yields a soluble ferrocyanide; while the solution of iron sulphocyanide may be concentrated and crystallised, or evaporated to dryness.—E. S.

Prussiates, Manufacture of, Improvements in [Use of Iron Sulphocyanide]. H. Bower, Philadelphia, U.S.A. Eng. Pat. 8381, April 27, 1895.

POTASSIUM (or sodium) carbonate, iron, and animal matter are mixed and heated, as in the ordinary process for obtaining a cyanide, but towards the end of the operation small portions of iron sulphocyanide (such as that obtained by the process described in the preceding abstract) are added at intervals. The yield of cyanide is thus increased.—E. S.

Cyanides and other Cyanogen Compounds, Manufacture of, Improvements in. W. P. Thompson, London. From J. Finlay and E. W. Derry, Johannesburg, South African Republic. Eng. Pat. 10,442, May 27, 1895.

A MIXTURE in about equal parts is made of "carbon, alkali, alkaline oxide or carbonate, or alkaline earths, preferably barium carbonate," which mixture is strongly heated in a current of air deprived of oxygen and sulphur dioxide. The formation of cyanates is stated to be thus prevented. On lixiviating the melt, a solution containing barium cyanide, sulphocyanide, and hydroxide is obtained. A slight excess of a chlorate or permanganate is added, and a current of deoxygenised air and carbonic acid gas is passed through the heated solution, when barium carbonate is precipitated and hydrocyanic acid and sulphur dioxide are evolved. The hydrocyanic acid is condensed and added to a strong solution of caustic soda kept at 40° F., from which crystals of sodium cyanide are obtained without the aid of alcohol. After the condensation of the hydrocyanic acid, the accompanying nitrogen and sulphur dioxide are conducted over a mixture of the precipitated barium carbonate with carbon, heated as before described.—E. S.

Metallic Cyanides, Manufacture or Production of, particularly Cyanide of Potassium and of Sodium, Improvements in. C. Kellner, Vienna, Austria. Eng. Pat. 23,580, Dec. 9, 1895.

THE nitrate or nitrite of the metal of which a cyanide is required, is subjected, either alone or mixed with carbon free from nitrogen, to the action of an electric arc between carbon electrodes. An electric melting furnace of known construction may be used.—E. S.

Chlorates, Improvements in the Manufacture or Production of Alkaline. C. Kellner, Vienna, Austria. Eng. Pat. 23,591, Dec. 9, 1895.

CHLORATES of the alkali metals are produced from the chlorides by electrolysis, without use of a diaphragm, by suspending in the electrolyte a suitable oxide or hydrate, such as calcium hydrate, not soluble in the liquid. The function of such a hydrate is to effect the transference of the chlorine from the anode to the cathode, without participating in the conduction of the current. The oxide is kept agitated during the process. A modified process consists in separating a hydrate, as of calcium or magnesium, from its chloride by electrolysis, and then converting the chlorate so formed into the required alkaline chlorate by the addition of a solution of the corresponding chloride. In this manner calcium and magnesium chlorides occurring as waste products may be utilised in the production of alkaline chlorates.—F. S.

PATENTS.

Glass, Producing Indelible Pictures upon; A Method of. F. Schachinger, Munich. Eng. Pat. 6602, March 30, 1895.

AN emulsion of gelatin and "chromate" of potassium, &c., containing a sufficient quantity of ceramic black colouring matter, is spread on the surface of the glass, exposed under a negative, and treated in the usual manner. The resulting picture is finished in pigments and burnt.—F. H. L.

Producing Markings, Engravings, or Ornaments on Glass and Glazed Ware, Improved Means or Method for Permanently. C. G. Pickering and C. F. B. Birchall. Wood Green, Middlesex. Eng. Pat. 6790, April 2, 1895.

THE material is wetted with water or other liquid, and it is then "scratched or engraved at the parts to be marked or ornamented by an aluminium point, stick, or disc to any design required." A thin coating of metal is thus obtained having a silvery appearance.—F. H. L.

Sheet Glass, A New Product for Use in Substitution of, for Windows, Engraved Glass, Painted Glass, Blinds, Curtains, and other Purposes. J. Badon, Brussels. Eng. Pat. 24,263, Dec. 18, 1895.

A FABRIC, such as tulle, muslin, or wire gauze, is coated on both sides with a bichromated film of gelatin, &c., which is rendered insoluble by the action of light. Pigments may be incorporated with the coating liquid if desired; but if the incorporated mixture is to be finally treated with oil varnish, the use of the bichromate is not necessary. The designs are printed by photographic or lithographic processes.

The advantages claimed for the new product are:—Cheapness, insolubility and impermeability to atmospheric influences, flexibility, and suppleness.—F. H. L.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Slag Cement in Germany. F. H. Mason. U.S.A. Consular Reports, Feb. 1896, 224—228.

THE report details certain historical facts concerning the production of slag cement, and states that frequent failures in manufacture having brought the material into disrepute and having caused the Association of German Cement-makers to agree not to use it, great difficulty has been experienced in continuing the production. In the valley of the Saar, however, where slag of the correct composition and properly granulated can be obtained, there are two factories, one at Malstatt and another at Nennkirchen. The slag cement here made sells in lots of 50 tons, at 5.35 marks per barrel of 150 kilos. (Slag cement being lighter than Portland). Carefully made slag cement has given excellent results at various official testing stations, and can be used for foundations and under water, but preferably not for work exposed to air and sun. A good

deal is utilised for making paving tiles, which consist of a mixture of gravel, sand and cement, moulded by hydraulic pressure. The cost of these tiles is 81 cents per sq. metre.

—B. B.

X.—METALLURGY.

"Cuban" [Copper Pyrites], Note on the Composition and Constitution of. R. Schneider. J. Prakt. Chem. 52, 1895, 555.

THE physical properties of the mineral analysed agree with those first described by Breithaupt, and the empirical formula obtained, CuFe_2S_3 , is the same as found by Scheidhauer, but differs from that given in Dana's System of Mineralogy, CuFe_2S_4 , which resulted from an analysis of mineral from presumably the same source (Barraconao, in Cuba). There are evidently two different minerals. The author proposes to call CuFe_2S_3 , "Cuban," and CuFe_2S_4 , "Barraconite" or "Cunpropyrites." Cuban is to be regarded as $\text{Cu}_2\text{S} \cdot \text{Fe}_2\text{S}_3$, copper pyrites, in which two-thirds of the cuprous sulphide are replaced by the isomorphous ferrous sulphide,—

—A. C. W.

Aluminium Alloys. F. G. Andrews. Dinger's Polyt. J. 1896, 299, 24.

OF the binary alloys with gold, that with 94 per cent. Al is white, but more brittle than pure aluminium. The 90 per cent. alloy is harder, and must be worked at a higher temperature; it ranges from clear violet to brown in colour. With 85 per cent., the colour is white, with a faint violet shade, and the metal is very soft and fine-grained. With 50 per cent., the alloy is violet, soft, and porous; whilst with 22 per cent. it is very brittle, and its colour lies between red and violet. With 20 per cent., the colour is a blue-violet, and with 10 per cent. it is again roseate. Alloys with but little aluminium show a clear violet colour in the blow-pipe flame. The aluminium-gold mixtures have no practical value except for decorative purposes. The alloy of 50 per cent. gold, 5 aluminium, and 45 copper has the colour and lustre of 14 carat gold, but soon loses its lustre.

Of the silver-aluminium alloys, those containing 4 to 8 parts of silver are almost silver-white, are harder than aluminium, and are not brittle, but take a good polish and are very useful, especially for medals, jewellery, and decorative work.

With nickel in equal proportions, aluminium gives a dark grey, porous, and brittle alloy of no practical use. But the alloy of 66 per cent. Cu, 24 per cent. Ni, and 10 per cent. Al takes a good polish and has the colour of 10 carat gold. That of 55 per cent. Cu, 33 per cent. Ni, and 12 per cent. Al has a fine golden-brown colour; whilst that of 72.5 per cent. Cu, 21.25 per cent. Ni, and 6.25 per cent. Al is similar, but richer and deeper in tint. These ternary alloys are tenacious, hard, and fine-grained. In making the alloys, the aluminium is added only when the other metals are fully melted.—W. G. M.

Lead, Desilverised by Pattinsonising and by Zinc; Use of. Freiberg. Jahrb. Berg- u. Hüttenm. Zeit. 1896, 55, 32.

PATTINSONISED lead is commonly preferred for the construction of vitriol chambers, and even for the manufacture of white lead. An experiment made in England gave results equally satisfactory with both kinds. Even 0.003 to 0.005 per cent. of Bi interferes in the white-lead manufacture, whilst 0.003 per cent. of Cu or 0.006 per cent. of Ag imparts a reddish tinge to the product; 0.1 per cent. Sb adds to the time required for corrosion, but even 0.5 per cent. does not affect the colour. As compared with Pattinsonising, the zinc process gives a lead with only one-third of the silver, and almost free from copper, but containing the whole of the bismuth. Lead containing even 2 per cent. of Bi may yet be rolled without difficulty to sheet 0.5 mm. in thickness. Only one Pattinson apparatus is left in Germany—at Halsbrücke. The composition of certain varieties of commercial lead is given in the following table, of which only the last was made by Pattinson's process.

	Sb.	Cu.	Fe.	Zn.	Ag.	Bi.

PATENTS.

Precious Metal [Gold and Silver], Improvements in the Extraction of, from their Ores or from Compounds containing the same. J. Maclear, London. Eng. Pat. 4004, Feb. 25, 1895.

The claim is for the use of cyanide of potassium, or other cyanide or cyanogen compound, from which free hydrocyanic acid can be liberated by the addition of an acid, containing cyanuric acid or a cyanurate. The proportions vary according to the nature of the ore. Five parts of cyanuric acid to 100 parts of cyanide give good results when the gold is fine and free, whilst a larger proportion is necessary in the case of refractory ores or when the gold is coarse, although the proportion of 25 to 100 parts never need be exceeded. The cyanuric acid may be added as such, or as a cyanurate, to the cyanide solution, or produced *in situ* by the action of a hypochlorite or hypobromite upon hydrocyanic acid or a cyanide.

The advantages obtained by the presence of cyanuric acid are: the more active and rapid solution of the gold, the avoidance of the objectionable action of the cyanide solution on the base metal compounds, and the smaller quantity of cyanide required. In the case of ores containing much silver as sulphide, the solution is rendered more alkaline than in the case of ores carrying the gold and silver in a metallic state.—A. W.

Annealing or Tempering Furnaces, Improvements in and connected with. F. T. Franke, Dessau, Germany. Eng. Pat. 244, Jan. 4, 1896.

The annealing pot is heated in a circular brick chamber in which there is a fire-gate with the usual accessories. Instead of the heated gases, &c. being allowed to pass out at the top of the chamber after having heated the annealing pot, they are now made to pass down a vertical pipe through the centre of the pot into a flue underneath. By this means more uniform heating of the castings is obtained, and the overheating of those lying near the walls of the annealing pot is avoided.—A. W.

Gold-plated Wire, An Improved Method of and Device for Manufacturing Seamless. F. Kammerer, Pforzheim, Germany. Eng. Pat. 1741, Jan. 24, 1896.

The present method of covering the copper or brass wire with gold-foil, and rotating and heating the same, causes the gold to become alloyed with the base metal, and thus lose its value in respect to colour. The author overcomes

this drawback by welding the gold-foil to the wire by the application of heat and pressure. After wrapping the gold-foil round the ground wire, which should be preferably square or quadrangular, the whole is placed in a matrix consisting of conveniently shaped pieces of a suitable material, and, after binding together with a wire, strongly heated in a furnace. Whilst hot the matrix is subjected to outside pressure, whereby the gold is pressed on to the sides of the wire, to which it adheres without showing any appearance of a seam, and without losing its colour.—A. W.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Electrolysis without Diaphragms. W. Bein. Zeits. f. Elektrochem. 1895—96, 2, 346—347.

A METHOD depending upon a principle of stratification. When no diaphragms are used, the products of electrolysis remain in the neighbourhood of the electrodes, provided that the arrangements are such as to exclude currents and eddies due to differences in specific gravity or to the evolution of

gases. The products of electrolysis then remain separated from each other by a zone of undecomposed liquid, and can be run off by taps or siphons. A diagram of such an arrangement is shown in the figure.—D. E. J.

Nitrobenzene, Electrolytic Reduction of. K. Elbs. Zeits. f. Elektrochem. 1896, 2, 472—475.

In preparing paramidophenol by Gattermann's method (Ber. 26, 1847) it is difficult to obtain a good yield, and aniline is always formed simultaneously. In dilute sulphuric acid the nitrobenzene is so slightly soluble that the time required is excessive, and the yield is lessened by secondary reactions, whilst with strong acid paramidophenol sulphonic acid is formed. Aniline is always present in the product to the extent of from 40 to 100 parts per 100 of paramidophenol. The sulphuric acid acts chiefly as a solvent, and as such may be advantageously replaced by acetic acid; a greater yield is obtained, but with it a proportionate amount of aniline. Several experiments are recorded:—

(1.) With (50 per cent.) acetic acid as anode solution, and 81 sq. cm. of platinum cathode in 200 c.c. of (50 per cent.) acetic acid, 5 c.c. of strong sulphuric acid, and 30 grms. of nitrobenzene, a current of 6—7 volts (between electrodes) and 0.1—0.6 ampère, a temperature not exceeding 60° C., and a duration of 10 hours, azoxybenzene, aniline, paramidophenol, and a little paramidophenol sulphonic acid were formed.

(2.) With (90 per cent.) acetic acid as anode liquid, 100 c.c. of (90 per cent.) acetic acid, 10 c.c. strong sulphuric acid, and 40 grms. nitrobenzene as cathode solution, and a duration of 20 hours, the other conditions being unaltered, diacetyl paramidophenol and some acetamidophenol were formed.

(3.) With 3 vols. of strong sulphuric acid and 1 vol. of water around the anode, and 72 grms. of glacial acetic acid, 45 grms. of strong sulphuric acid, and 36 grms. of nitrobenzene around the cathode, using a current of 3.5 volts and 2—2.5 amperes at a temperature of 80°—85° for nine hours, with a platinum cathode as before,—the products were 4 grms. of aniline, 7.5 grms. of paramidophenol, and 1 gm. of paramidophenol sulphonic acid with some colouring matter. By working at a lower temperature (50°—55°) the yield was reduced markedly, and at 25° very greatly.

(4.) By substituting a lead cathode of 100 sq. cm. for the platinum, and using 40 grms. of nitrobenzene instead of 36 grms., the conditions being otherwise as in experiment 3 (temperature 80°),—a better yield was obtained, but the proportion of aniline was greater, viz., aniline 6.5 grms., paramidophenol 6.5 grms., the weight of other products being unchanged. A prolongation of the time to three days, led to the formation of aniline 23 grms., paramidophenol 9 grms., and paramidophenol sulphonic acid 1 gm., with a trace of colouring matter.

(5.) A three-day experiment on the lines of experiment 4, but with original platinum cathode instead of lead, and with current of 3—4 amperes, and temperature 85°, gave as the products:—Aniline 8 grms., paramidophenol 19 grms., paramidophenol sulphonic acid 0.5 gm., and colouring matter 0.2 gm.

It appears that the nitrobenzene is reduced by the lead sponge on the lead cathode without any appreciable formation of lead sulphate, which would be again reduced by the hydrogen ions liberated. This is in harmony with former observations by the author with zinc cathodes. The successive stages of reaction suggested by these experiments are as follows:—Nitrobenzene is first wholly, or in part, converted into azoxybenzene, which by the action of strong sulphuric acid slightly warmed, becomes p-oxazobenzene, and this in turn is converted by hydrogen into aniline and paramidophenol.—W. G. M.

Persulphuric Acid in Lead Accumulators. K. Elbs and O. Schönherr. Zeits. f. Elektrochem. 1896, 2, 471—472.

REPLYING to three objections raised by Schoop in regard to their previous criticisms on the Darreus theory (see this Journal, 1895, 14, 581), the authors first defend their use of platinum electrodes by showing that *ceteris paribus* more persulphuric acid would be formed on them than on lead plates, and by reiterating their statement that sulphuric containing persulphuric acid will even convert a film of lead peroxide into sulphate. Secondly, they endeavour to meet Schoop's hypothesis based on the possible action of nascent persulphuric acid by asking, how the residue of this acid differs from that of sulphuric acid (HSO_4) in moderately dilute solutions? These are well known to peroxidise lead and its salts. The third objection was that they regarded as lead sulphate the white precipitate formed on mixing lead nitrate and ordinary ammonium persulphate solutions, although it rapidly became brown by peroxidation. To this the authors reply that lead persulphate is soluble and easily decomposed, that ordinary ammonium persulphate contains sulphate, and that any lead sulphate formed would naturally become rapidly covered with brown peroxide under these circumstances.—W. G. M.

Hydroquinone, Electrolysis of. L. Liebmann. Zeits. Elektrochem. 1896, 497—499.

THE electrolysis of aniline gives a good yield of aniline black, but experiments conducted with the object of converting it by further electrolysis into quinone only gave negative results. Even hydroquinone on electrolysis only gives very small quantities of quinone, the chief product being quinhydrone. The electrolysis of the cold saturated solution of hydroquinone containing a few drops of sulphuric acid, is performed in a U-tube with platinum or

carbon electrodes, the current employed being obtained from accumulators at a pressure of 12 volts, and can vary from 0.02 to 2 amperes without affecting the result. About 10 minutes after commencing the operation, quinhydrone separates at the anode, and after one crystallisation from 75 per cent. alcohol the substance is pure. With regard to the yield of quinhydrone, it would appear that the amount produced by electrolysis is approximately the same as that obtained by the use of oxidisers such as ferric chloride or potassium ferricyanide. Similar results are obtained by the use of an alternating current (5,400 alternations per minute at 120 volts) for electrolysis, the quinhydrone, however, separating in this case, together with hydrogen, in long needles, at both electrodes, sufficiently pure for analysis.—T. A. L.

Electric Furnace for 1,000 Amperes. J. Pfleger. Zeits. f. Elektrochem. 2, 367.

Electrical Storage Batteries, Improvements in and connected with. W. J. S. Barber-Starkey, Bridgnorth, England. Eng. Pat. 7315, April 10, 1895.

THE improved plates are formed of a number of discs, washers, or the like, threaded on lead tubes or rods and suspended from a transverse bar. When the tubes are employed they may be strengthened by a wooden or vulcanite core. The discs, which are punched from sheet lead, are corrugated radially, and arranged so as to afford space for the lead oxide paste. The lodgment for the active material may also be secured by stringing on the core large and small discs alternately, or by any other device.—G. H. R.

Secondary and Primary Batteries, Improvements in the Active Material for. A. Schanschiff, Norwood, England. Eng. Pat. 8081, April 23, 1895.

THIS improvement relates to the preparation of the non-metallic portions of the paste described in Eng. Pat. 12,045 (this Journal, 873, 1895). The plates are constructed of a paste composed of two parts by volume of appropriate metallic salts, say minium or litharge, and one part by volume of carbon, prepared by mixing 50 parts of sugar solution with 35 parts of strong sulphuric acid. The sugar solution is made by mixing 100 parts by weight of sugar with 30 parts of water. Instead of sugar, treacle or other hydrocarbon may be used. The carbon so prepared must be kept for a day or so to cool before being mixed with the metallic oxides or salts. For secondary batteries, this mixture of the carbon and metallic oxides is worked into a paste of the consistence of putty with an aqueous solution of the sulphuric acid of 1.1° B., and is ready to be applied to the plates. In single- and double-fluid batteries this prepared carbon is used instead of the retort carbon hitherto employed.—G. H. R.

Electrical Accumulators, Improvements in Oxidising Lead and Lead Compounds for the Construction of. H. Leitner, Niederschönhausen, Germany. Eng. Pat. 18,034, Sept. 26, 1895.

THE improvement consists in treating lead or lead compounds with an alkaline hypochlorite, and subjecting them to electrolysis, thus oxidising the mass throughout. The paste of which the plates are formed is composed of lead oxide and about 10 per cent. of retort carbon, both in powder, and intimately mixed, to which is added sufficient glycerin to form the substance technically known as glycerin-lead oxide putty. A number of tubes formed of rolled-up foil are inserted into the mass, and the whole is pressed into a carbon cylinder, which is then immersed in a saturated solution of sodium hypochlorite, causing the oxidation of the surface lead oxide to peroxide. The passage of an

electric current through the mass causes the lead and lead oxide to be thoroughly peroxidised and the binding material to be removed. It is claimed that the carbon mixed in the paste hastens the oxidation of the lead and the oxide, and is itself eventually oxidised away, leaving a porous, coherent mass of peroxide.—G. H. R.

Insulating Compositions for Electrical Purposes, Improvements in the Manufacture of. C. J. Grist, London. Eng. Pat. 22,574, Nov. 26, 1895.

Hemp, jute, cotton, or any animal or other fibre in which the fibres can be made distinct and similar, are carded, cleaned, and dried by hot air, and then dipped into cold linseed or other drying oil which has been heated up to 100° F. with the addition of litharge or other suitable drying agent. The oil must not be boiled for more than six hours at any one time, and must be kept in motion continuously. On removal from the oil, the fibres are pressed in an extractor to remove the superfluous oil, and then are spread loosely on wire gauze or netting, when the adhering globules of oil are thoroughly dried and oxidised by means of hot air. This process is repeated three times, but not more, and then the fibres are masticated between rolls of different diameters till they assume a homogeneous condition. The material is placed in crushing rolls, which must not be heated, and at least 15 to 20 per cent. of powdered sulphur is added, care being taken that the material does not heat. When it has been thoroughly incorporated, the substance is allowed to cool, and is then again placed between the crushing rolls, when from 5 to 25 per cent. of gutta-percha or wax is added to impart cohesion, and the material is rolled into sheets ready for use.—G. H. R.

Galvanic Batteries, Improvements in or connected with [Current Regulation]. A. C. Iwanowski, Kiev, Russia. Eng. Pat. 24,172, Dec. 17, 1895.

In the improved battery the cells, which are supported in a suitable frame, are connected from their under surfaces with a main pipe by means of tubes. This pipe has a tap at one end, and at the other is connected with a closed vessel of similar form to the cells. The vessel is connected by means of a pipe and cock with a reservoir, also hermetically sealed, which contains the electrolyte, and is supplied with a valve controlled by a spring and electro-magnet. When the cock is turned, the electrolyte flows through the vessel into the cells until checked by the vacuum formed in the reservoir. When the current falls below a predetermined strength, the electro-magnet can no longer restrain the spring, and the valve opens, admitting air, and the electrolyte rises in the cells until the current has regained its normal strength owing to the fresh surfaces of zinc and carbon exposed to the electrolyte, when the valve closes as before. This action repeats itself until the cells are full, when the supply tap is closed and the spent electrolyte is drawn off.—G. H. R.

Metallic Cyanides, particularly Cyanide of Potassium and of Sodium, Manufacture or Production of, Improvements in. C. Kellner, Vienna, Austria. Eng. Pat. 23,580, Dec. 9, 1895.

See under VII., page 274.

Alkaline Chlorates, Improvements in the Manufacture or Production of. C. Kellner, Vienna, Austria. Eng. Pat. 23,591, Dec. 9, 1895.

See under VII., page 275.

Electric Accumulators, Improvements in and relating to [Lead and Glass Fabric]. R. J. Gulcher, Charlottenberg, Germany. Eng. Pat. 130, Jan. 2, 1896.

The improved plates are made of a fabric formed by interweaving lead wires as the warp, and threads of glass cotton, glass, or quartz as the weft. The material is cut into pieces of suitable size, and the lead wires are bared for a short length, top and bottom, and inserted into a specially arranged mould, into which molten lead is poured to form a frame round the free ends of the lead wires, and also preferably on the two side edges. The fabric is impregnated with the active material in any suitable way, and the plates

thus formed are wrapped separately in a layer of glass cotton, and suspended between two supports connected by plates and bars.—G. H. R.

(B.)—ELECTRO-METALLURGY.

Electricity, Uses of, in Metallurgy. W. Borchers. Zeits. f. Elektrochem. 1895-96, 2, 368-372.

BEFORE smelting, many ores have to be submitted to processes of preparation, and we find that even in these preliminary operations electricity is of service. The magnetic and non-magnetic portions of a mixture can be separated by electro-magnetic contrivances, of which 170 have already been patented in the United States. Electro-magnetic preparation has been applied chiefly to ores of iron, lead, and zinc. In order to exhibit the nature of the many metallurgical processes in use and the part played by electricity in them, the author exhibits in a tabular form the various processes for reducing and separating metals extant. The table is reproduced in simplified form on next page. Empty spaces opposite the name of a metal indicate that the methods of the corresponding vertical column are not applied to it. Spaces ruled with fine vertical lines indicate methods in which electricity is not used. Spaces ruled with thick horizontal lines indicate electrical methods. We first come to those under the head of reduction of oxides by heat; in these cases, however, electricity is only employed as a means of producing a high temperature. But it is important to notice that *all* oxides (naturally with the exception of carbon monoxide) can be reduced by this method in presence of carbon. The Cowles process of manufacturing aluminium-bronze was the first important application of this principle. The author has shown that chromium, manganese, and tungsten can be prepared in the same way, although chromium and tungsten have a very high melting-point. In the chemical decomposition of sulphides and salts, electrical methods have found no application; but after this we come to processes which are entirely electrical. It will suffice to point out that the only metals not included in the columns for electrolysis of aqueous solutions and fused compounds are iron, mercury, and tungsten. Even these can be prepared electrolytically, but as yet the electrical methods have not been able to compete with the others. Among present applications of electrolysis may be mentioned the refining of metals and the manufacture of metallic objects (Elmore, Klein), the reduction of aluminium, the separation of gold and silver, the extraction of gold by the cyanide process and electrolysis, electro-deposition of zinc, &c. Hitherto electricity has played but a small part in the great iron industry, but strenuous efforts are being made to apply it both in the preparation of the raw material and in the subsequent processes of manufacture.—D. E. J.

Electric Furnace [Iron and Steel]. R. Urbanitzky. Zeits. f. Elektrochem. 1895-96, 2, 350-354.

In the blast-furnace method of reducing iron, the metal takes up impurities such as sulphur and silicon, and these are not entirely removed in subsequent treatment by the Bessemer or Martin process. The present methods of smelting must hold the field for ordinary grades of iron; but when purity is of importance, and when special qualities of steel are required, it will probably prove advantageous to prepare pure iron by electrical methods of reduction and to carbonise this subsequently. A furnace suitable for this and similar purposes is described. It is lined with a basic lining, like a Bessemer converter; this is non-conducting and almost infusible, and keeps the iron free from impurities. In the Heroult furnace used at Neuhausen the positive carbon is vertical, and the material to be fused has to be introduced into the narrow space between this and the walls of the furnace. It is preferable to have a positive electrode consisting of four carbons arranged symmetrically about a vertical axis and inclined at about 20° to it. These can be raised so as to produce an electric arc, or lowered so as to dip into the fused mass; they can also be rotated backwards and forwards so as to ensure a uniform distribution of the heat. The bottom of the furnace is insulated and forms the negative electrode;

Zinc and Lead from Mixed Ores, Method for Extracting
R. Lorenz. Zeits. f. Elektrochem. 2, 1895-96, 318-337.

MOST zinc ores contain some lead, and most lead ores contain some zinc. The processes of reduction commonly used are suitable for the one metal or for the other; hence in dealing with mixed ores it is necessary to submit them to a tedious preliminary process of preparation, so as to obtain grades of ore containing chiefly the one or the other metal. The electro-deposition of zinc from aqueous solution requires a comparatively high E.M.F., and the metal is apt to be deposited in a spongy state. These and other difficulties encountered in endeavouring to separate the dissolved metals by electrolysis in the usual way have induced the author to try the electrolysis of mixed fused salts (chlorides) of the two metals. He finds that fused zinc chloride can be electrolysed at a temperature at which neither the salt nor the metal volatilise; the molten metal

sinks below the fused salt and forms a good conducting cathode. But the preliminary experiments were not promising: the peculiar behaviour of zinc chloride had to be studied with some patience before success was attained. For when one endeavours to electrolyse fused zinc chloride in a porcelain crucible between carbon electrodes, an abundant evolution of gas is observed. The salt offers a very high resistance and behaves much as if it were a non-conductor. The contents of the crucible froth over, and no zinc can be found either on the cathode or at the bottom of the crucible. After the operation the salt is found to be strongly basic. Addition of common salt does not help matters, nor does the use of a higher E.M.F. The trouble is due to the presence of water, which is contained in zinc chloride even when it has been fused and kept in closed vessels. But the salt can be electrolysed with difficulty as follows. It is placed in a V-shaped tube of hard glass and heated over a Bunsen flame until it no longer froths. A carbon electrode is then introduced into each limb, the negative one reaching to the bottom, and the positive higher up. On passing the current, there is at first a rapid

evolution of gas, showing that water is still present. Presently the evolution of gas at the negative electrode diminishes, and the conductivity of the electrolyte rapidly increases. The metal now begins to be deposited as small fused globules, which drop to the bottom of the tube. If chemically pure zinc chloride be required, the operation should be allowed to go on a little longer, when the regulus will contain all traces of metals more electro-positive than zinc. The fused salt can then be poured out (leaving the regulus behind) into a second bent tube previously dried and heated. If the electrolysis be continued in this second tube, there is again a large evolution of gas at first, showing how eagerly the salt absorbs water from the atmosphere. (The author considers it the most strongly hygroscopic substance in existence—more so than phosphorus pentoxide.) Zinc thus prepared is absolutely pure. The pure fused chloride is a mobile, perfectly clear, highly refractive liquid, whereas ordinary fused chloride forms a syrupy, viscous mass.

The electrolysis of fused lead chloride offers no difficulties, and can be carried out as described above. Cadmium chloride can be electrolysed in the same way; but as the boiling point of cadmium is only about 900° and the melting point of its chloride is about 540°, care must be taken not to overheat the tube.

Fused mixtures of chlorides can be fractionally electrolysed. From zinc chloride (or lead chloride) containing silver chloride, the silver is first deposited. From mixtures containing lead and zinc, the lead is first deposited. Copper is deposited before zinc. The separation of the metals is not much affected by the E.M.F. used. The following table gives the results of a separation of lead and zinc by fractional electrolysis of the fused chlorides. The current used was 0.5 ampere. The second column gives the number of ampere-minutes reckoned from the beginning of the electrolysis, and the subsequent columns the percentage composition of the regulus:—

Fraction.	Ampere-Minutes.	Pb.	Cd.	Zn.
1	20	97.34	1.35	1.30
2	115	14.71	0.62	85.54
3	175	1.30	2.55	96.15
4	215	1.23	1.37	97.30
5	335	0.00	0.00	100.00
6	455	0.00	0.00	100.00

The cadmium must have been present as an impurity in the materials used. Details are given of a similar fractional electrolysis of zinc chloride containing silver chloride as well as lead chloride. The first fractions consist mainly of silver, but mixed with some lead and zinc. The next fractions consist almost entirely of lead. The proportion of zinc then increases, and the last two fractions consist of pure zinc. But if it be desired to remove and collect all the silver, a better plan is to start with a cathode of lead, on which the silver collects.

The author suggests that mixed ores of lead and zinc should first be roasted, then converted into chlorides, and the fused chlorides fractionally electrolysed so as to separate the silver, lead, and zinc successively (the silver as an alloy). The chlorine evolved at the anode is mixed with steam and led over glowing coke so as to convert it into hydrochloric acid according to the equation—

If the ore contains mainly zinc and but little lead, it can, after roasting, be at once treated with hydrochloric acid of moderate strength. When a large amount of lead is present, this treatment would not serve, for most of the lead would come down as lead chloride. Ores rich in lead are to be extracted with dilute acetic acid, then adding HCl until the lead and silver are precipitated. The cleared extract can be used for extracting further quantities of roasted ore until all the acetic acid is saturated. Finally the acetic acid is recovered by leading in hydrochloric acid gas, evaporating to dryness, and condensing the distillate.—D. E. J.

Lead Ores containing Zinc, Reduction of. R. C. Schüpphaus. Zeits. f. Elektrochem. 1895-96, 2, 347-348.

A criticism of a process described by W. Borchers in a previous number of the same journal. The process has been tried in Colorado and New Mexico, and has not there been found successful as a method of treating these refractory ores. The author regards another method, devised by E. Lungwitz, as more hopeful. The ordinary method of reducing zinc by distillation depends upon the fact that it volatilises at its temperature of reduction. Now, the boiling point of a liquid depends upon the pressure; hence, by increasing the pressure in the furnace, it ought to be possible to prevent the volatilisation of the zinc. The necessary pressure is the vapour pressure of zinc at its temperature of reduction (or at the temperature of the furnace). C. Burus has shown that at about 76 cm. pressure the boiling point of zinc rises about 1.5° C. for each centimetre. According to this the vapour pressure of zinc may be estimated at about 5 atmospheres at 1,500° C. But this temperature is never attained in zinc furnaces; 1,200° or 1,300° would be nearer the mark. Furthermore, zinc and lead alloy at high temperatures. Hence a pressure of 3 atmospheres should suffice. Lungwitz's process is based on these principles. If it proves as successful as the writer anticipates, the pure zinc will still be prepared electrolytically; but the starting point will not be zinc sulphate, but the zinc which separates out from the lead bath.

In a note appended to the above, W. Borchers maintains the opinions he had previously expressed.—D. E. J.

Zinc Extraction, Electrolytic. B. Neumann. Chem. Zeit. 1896, 20, 36-38.

The special difficulty in the way of electrolytic zinc extraction over and above those which occur in the treatment of other metals, is that the price of common zinc is M. 30 per 100 kilos., and of pure zinc only M. 31; whilst the cost of electrolysing zinc sulphate or chloride solutions with a current of 2.5 volts is M. 18.96 when steam-power is used, or M. 13.33 with water-power. With a surplus of from M. 11 to M. 17 per 100 kilos. to pay for roasting, leaching, &c., the process cannot compete with the distillation method for ordinary ores. It may be applicable either to ores too poor to treat in the usual way, or to those containing much galena and silver, which give difficulty in mechanical preparation; or it may be applied to roasted pyrites containing too much zinc to render it useful in the iron industry; or, finally, to waste zinc products.

In practice the electrolyte is prepared with difficulty, as the anhydrous or basic zinc sulphate from the roasted ores dissolves very slowly, and is accompanied by iron, which interferes with the deposition of pure zinc, and is not easily removed. The ferrous oxide is not precipitated by the zinc oxide with which the ferric compound is ordinarily thrown down, nor is it completely peroxidised by blowing air through the hot solution, even for 24 hours (Chem. Zeit. 1895, 19, 221). This solubility of interfering substances negatives the use of Luckow's process, in which the roasted ore is made the anode. But, as the treatment of argentiferous blende is the most desirable, it must be remembered that roasting at a low temperature leads to the deficient solubility of zinc compounds, whilst very strong roasting may lead to a loss of 70 per cent. of the silver. Silver sulphate alone is very slightly volatile, but the presence of zinc compounds has been shown by Malagati and Durocher to increase the loss. The roasting of this mixed ore, followed by the leaching out of the zinc and the smelting of the residual silver-lead compounds, has been tried frequently, but with no success. A chloridising roast which is successfully applied to the treatment of zinciferous burnt pyrites at Fährfurt-a.-d.-Lahn and at Duisburg is not applicable to these ores by reason of the loss of silver, which may amount to 60 per cent. After roasting, Ashcroft extracts zinc with ferric chloride solution (Zeits. Elektrochem. 1895, 2, 376), Heinzerling with magnesium chloride (Chem. Zeit. 1892, 16, 1864), Höpfner with carnallite, and others with calcium chloride; but these substances do not appear to present any advantages. Alkaline zincate solutions have been recommended by Kiliani, Burghard, and Höpfner, but no working results have been published.

Given a suitable solution, other difficulties arise during electrolysis. Unless the solution be constantly neutralised, the sulphuric acid formed at the anode soon causes a rough cathode deposit and a co-deposition of hydrogen. But if the solution be basic (and zinc sulphate solution readily dissolves a little of the oxide), a zinc sponge comes down, which prevents the rolling of the metal, and oxidises on re-melting. The same sponge is apt to deposit if the current strength be less than 150 amperes per sq. m. Mylius and Fromm (*Zeits. anorg. Chem.* 1895, **9**, 144), and Nahsen (*Berg u. Hütt. Zeit.* 1891, **50**, 383), consider that the sponge is due to the presence of oxygen, and that it contains oxide and basic salts; whilst others refer it to the formation of a zinc hydride. Copper, antimony, and arsenic (the latter even in such small quantities as 0.01 per cent.) interfere with the precipitation. The solution must be faintly acid; the best results are obtained with 0.016 per cent. of free sulphuric acid, but it is technically impossible to maintain the liquid at this strength. The presence of organic salts assists the deposition of zinc for analytical purposes; and the use of oxalic acid has been recommended by Pertsch (*Chem. Zeit.* 1893, **17**, 285), lactic acid by Jordis (*Zeits. Elektrochem.* 1895, **2**, 148), and acetic acid by Watt; but the cost of the process would be considerably enhanced by these additions, and no results have yet been published. To prevent the formation of slime, Lindemann (*Chem. Zeit.* 1895, **19**, 1357) suspends zinc sulphide in the solution, but it is doubtful whether the evolution of hydrogen sulphide in this way would lead to the desired result. Siemens and Halske (this *Journal*, 1893, 698) recommend for the same object hypochlorous or hypobromous acid. The use of diaphragms has failed by reason of the difficulty in finding a suitable material for the purpose. Lorenz (this *Journal*, 1896, 39) has attempted the electrolysis of fused zinc chloride. But apart from the difficulty in evaporating the solution and obtaining anhydrous salts, and in finding a durable material for the furnace, the process is technically unmanageable. In Lipine (Upper Silesia) the Silesian Act. Gesellsch. f. Bergbau has tried a process of Nahsen's for the extraction of zinc from blende ($\text{ZnSO}_4 + \text{K}_2\text{SO}_4$ or MgSO_4), and Speyer has shown (*Zeits. Elektrochem.* 1895, **2**, 46) that small quantities of 99.98 per cent. Zn were obtained, but the cost of production was prohibitive. Léfrange showed electrolytic zinc at Chicago, and according to Gouch (*Berg u. Hütt. Zeit.* 1895, **54**, 402) this process may yet give good results. An English company is erecting, near Sydney (N.S.W.), works to treat the Broken Hill ores (containing 25 per cent. Pb, 26 per cent. Zn, and 20 oz. Ag. per ton) by leaching out the zinc and electrolysing the sulphate; but it remains to be seen whether they will succeed, even with the cheap ore available. The electrolytic zinc at present in the market is not produced from ores, but either from zinc residues or from the comparatively valueless zinc chloride solutions of larger factories. Of the two available solutions, sulphate and chloride, the latter is to be preferred, because of the possibility of recovering the anode chlorine as a by-product.—W. G. M.

Electric Furnace for 1,000 Ampères. J. Pfleger. *Zeits. f. Elektrochem.* **2**, 1895-96, 367-368.

PATENTS.

Copper, Zinc, and other Metal Sheets, Strips, or Wires. Improvements in and Apparatus for the Manufacture of, Electrically. Cowper-Coles Galvanising Syndicate and S. O. Cowper-Coles, London. Eng. Pat. 2998, Feb. 11, 1895.

ACCORDING to this improvement the cathode consists of an endless band or its equivalent, which by means of rollers is caused to travel slowly through the electrolyte. The cathode may be formed of a thin flexible sheet or band of some metal, such as copper, or of a non-metallic material rendered conductive by a coating of plumbago or any suitable substance, and the band may be caused to pass, if desired, through a bath, which will prevent the undue adherence of the deposited metal thereto. Rollers are pro-

vided to strip the deposit from one or both sides of the travelling cathode, and the band or bands of metal so obtained are passed through rolls which divide the sheets longitudinally, and they are given any desired sectional form by means of dies or formers.—G. H. R.

Precious Metals, Improvements in Means or Apparatus for the Obtaining of, from Ores or Materials containing them. L. Pelatani, Paris, France, and F. Clerici, Milan, Italy. Eng. Pat. 24,803, Dec. 27, 1895.

THIS invention consists in an electrolytic cell constructed for facilitating the reactions required by a particular arrangement of anodes and cathodes, and of means whereby the liquids are kept in circulation during the electrolytic action. The bottom of the electrolytic vat, which is also the vessel in which the ore or other substance is dissolved, is lined with an insulating material, such as cement or ebonite, and is covered with a cathode formed of amalgamated copper or lead plates or of mercury. The two cylinders or drums are mounted one at each extremity of the inside of the vat, and support an endless band of nearly the same width as the vat and provided with agitators made of wood or other non-conducting material. In order to maintain a proper distance between the belt and the agitators and the cathode, any suitable stretcher or support is used. The belt may serve as an anode if made of a conducting material, or of an insulating substance rendered conductive by a suitable coating; or a fixed anode may be employed, and the belt may take the form of a wide-meshed trellis of non-conducting material passing with its agitating arms between the anode and the cathode. The solvent preferred is a dilute alkaline cyanide solution not exceeding 3 parts cyanide to 1,000 parts water, and this solution is rendered conductive by the addition of sodium chloride.—G. H. R.

Zinc from its Ores, A Process for the Electrolytic Production of. Siemens Brothers and Co., London. From Siemens and Halske, Berlin, Germany. Eng. Pat. 1575, Jan. 22, 1896.

THE zinc oxides resulting from the treatment of its ores or of calamine without such treatment, is dissolved in a solution of neutral aluminium sulphate, $\text{Al}_2(\text{SO}_4)_3 + 18\text{H}_2\text{O}$, and the solution thus obtained is electrolysed between insoluble anodes at a pressure of about 3 volts after impurities have been removed by known methods. Zinc is deposited at the cathode, and oxygen is evolved at the anode, while the basic aluminium sulphate is reconverted into neutral aluminium sulphate, which is ready to be used again. As no acid is formed, the deposited zinc is not redissolved, and therefore no diaphragm is required. The bath is best prepared by dissolving the zinc oxide in a warm solution containing from 100 to 150 grms. of neutral aluminium sulphate per litre.—G. H. R.

XII.—FATS, OILS, AND SOAP.

Fatty Substances, Saponification of. V. Cochenhausen, Dingler's polyt. J. 1896, **10**, 233-239.

THE paper is largely polemical, disputing certain statements of Lifschütz. The conclusions which the author seeks to establish may be enumerated thus:—The belief that many saponifiable materials, e.g., oleic acid, undergo decomposition (involving further consumption of alkali) when digested for a long time, and at a high temperature, with strong alcoholic potash, is unfounded. Such a reaction as that which oleic acid undergoes when fused with caustic alkali, does not, it is stated, occur under any ordinary conditions of saponification for analytical purposes. Similar constancy of results, in spite of varying procedure, obtains with wool fat, which is not gradually and increasingly acted on by caustic potash when small increments in temperature or time of digestion are made. It is incidentally shown that many samples of commercial oleic acid are very impure, containing much neutral fat and unsaponifiable matter.

Glycerin, The Manufacture of. F. Jean. Rev. de Chim. Ind. 1896, 7, 33—35.

MOST of the glycerin of commerce is manufactured by the hydrolysis of stearin with water and magnesia (1½ per cent.), under a pressure of 9—9½ atmospheres (a method stated to yield glycerin in a condition of greater purity than does the method with lime), or, more usually, with lime (3 per cent.) under a lower pressure.

For the hydrolysis of fatty oils, with a view to the utilisation in the manufacture of soap of the fatty acids produced, the process of Poulain and Michaud is also employed. It consists in heating the fatty oils under pressure with zinc oxide or zinc dust, and has the advantage of yielding, along with fatty acids in the free state, soap compounds, which do not require to be decomposed with sulphuric acid, as in the case of the magnesia and lime processes, but which may be at once converted into soda soaps, as the zinc oxide present in them is soluble in the caustic soda employed, and is removed in the waste lyes. The process has especial value for the treatment of palm oil, as it gives a mixture of fatty acids almost free from colour. A yield of 6 per cent. of glycerin is obtained when 3,000 kilos. of oil are heated with water and 10 kilos. of zinc dust for six hours under a pressure of 8—9 kilos. per square centimetre.

The recovery of glycerin from the waste lyes of the soap-works is, when the caustic lyes are prepared from soda-ash manufactured by the ammonia process, relatively simple. The waste lyes are neutralised with an acid, or treated with a salt, which will precipitate the albuminous, &c. matters present, and, after the removal of these, they are evaporated, to separate the salts, the residual glycerin being purified by distillation under reduced pressure.

With the waste soap-lyes from causticised Leblanc soda, the operations are more tedious and difficult, as the glycerin is in this case accompanied by sodium sulphide and thio-sulphate, in addition to the gelatinous and other organic matters, sodium carbonate, chloride, and hydroxide, ordinarily present. The sulphuretted compounds formed when such lyes are neutralised would, if measures were not taken to obviate this, render very impure the glycerin obtained on distillation. One of the methods proposed for dealing with these lyes, namely, that of oxidation with calcium hypochlorite, after neutralisation, is unsatisfactory, as it gives a product containing objectionable oxidation derivatives. Another method—decomposition with iron and hydrochloric acid—is more satisfactory. Droux and Depouilly have suggested as a practicable method, the treatment of the magma, left on evaporation of the lyes, with oleic acid,

in an atmosphere of carbon dioxide, at 170°—175°, in an apparatus provided with an agitator. Under these conditions the glycerin combines with the oleic acid, forming an oil which contains twice as much glycerin as natural olein. This is washed with water and then hydrolysed.—E. B.

Fatty Bodies, Unsaturated, Action of Sulphur on.

J. Altschul. Zeits. f. Ang. Chem. 1895, 535.

BENEDIKT and UZER showed that on heating oleic acid with sulphur to between 200° and 300° C., sulphuretted hydrogen was evolved through the conversion of oleic acid into sulpholeic acid, but it appears that the action of sulphur upon unsaturated fatty bodies and at temperatures at which re-evolution of sulphuretted hydrogen takes place, has never been investigated. On heating oleic acid with 10 per cent. of sulphur to from 130° to 150° C., the sulphur gradually dissolves, and does not crystallise out again on cooling. The oleic acid thus treated dissolves in ether without any sulphur separating out. In the same way all unsaturated fatty oils behave. That in this treatment the sulphur has entered into combination with the fatty acids, is proved by the observation that the saponification of oils treated with sulphur in the manner above described, leads to the formation of salts of true sulphuretted fatty acids, which can be obtained from them in the free state by the action of acids. Since in the reaction between sulphur and oils, no sulphuretted hydrogen is evolved, the sulphuretted compounds obtained must be addition products. The saponification of these sulphuretted compounds of the fatty oils and acids must, however, be carried out in the cold, as their hot saponification is accompanied by a more or less complete elimination of the sulphur. Oils that are not very readily saponifiable, such as linseed oil, receive an admixture of cocoa-nut oil, when their complete saponification at a temperature of 25° C. is easily effected. It is very probable that these sulphur addition products of the unsaturated fatty oils are closely analogous to the oxidation products of those bodies which are obtained either by exposing them to the air in thin layers at ordinary temperatures, or by blowing air through them at higher temperatures. For the latter, Henriques showed that they can be converted into india-rubber substitute, with a much smaller percentage of chloride of sulphur than the oils in their original condition require, and exactly the same is true for the sulphuretted oils.—C. O. W.

Fatty Bodies, Unsaturated, Action of Sulphur on.

R. Henriques. Zeits. f. Ang. Chem. 1895, 691.

ALTSCHUL's statement (see preceding abstract) that the treatment of unsaturated oils with sulphur at low temperatures results in the formation exclusively of addition products, is not quite correct, neither can it be said that at high temperatures only substitution products are formed. Indeed substitution and addition seem always to take place concurrently, though the former is favoured by high temperatures, the latter by low ones. The high iodine numbers of the fatty acids obtained by the saponification of "brown" india-rubber substitutes are in no way opposed to the assumption of these substitutes being addition products. Altschul's method of saponifying his sulphuretted oils in the cold, in conjunction with a certain quantity of cocoa-nut oil, is not very satisfactory for analytical purposes. The same result is better obtained by saponifying the sulphuretted oil, dissolved in petroleum spirit, with standard alcoholic soda. Analysing in this manner a number of sulphuretted oils, cold saponification always yielded fatty acids containing more sulphur than when the saponification was carried out at higher temperatures, but the amount of sulphur remaining in the fatty acids was always rather less than the total sulphur contained in the substitute, so that the latter must either contain free sulphur, which is highly improbable, or it must be admitted that even in the process of cold saponification, sulphur, in the form of hydrogen sulphide, is eliminated.—C. O. W.

Transparent Soap, Alcohol used in the Manufacture of; Denaturing the latter. R. Hirsch. Die Chem. Ind. 1895, 18, 475—476.

It has recently been permitted—tentatively at least—to employ, in the manufacture of transparent soap, spirit

denatured by means of methyl alcohol ($\frac{1}{2}$ per cent.), castor oil ($\frac{1}{2}$ per cent.), caustic soda solution ($\frac{1}{4}$ per cent.). These ingredients, according to the author, have no injurious effect on the transparency and odour, &c., of the finished soap. He suggests, however, that in order to render the spirit completely undrinkable, larger proportions of castor oil (10 per cent.), and of soda solution (2 per cent.), should be added; whilst the methyl alcohol, on account of its high price, might be replaced by various essential oils ($\frac{1}{2}$ to 2 per cent. of bergamot, &c.). The latter are required in any case, as scent, and would not therefore add to the total cost.

Treu and Nüglisch (*ibid.* 1895, 499–501) severely criticise the author's suggestions,—chiefly on the score of costliness,—and state that most of the ethereal oils in contact with alcoholic caustic soda, would be gradually decomposed or more or less spoiled. To this Hirsch replies (*ibid.* 1896, 80), pointing out that in alcoholic solution castor oil and soda rapidly react to form soap, so that no injury can result to the essences added.—H. T. P.

Oil-Mill Presses, Anglo-American, Improvements in the Construction and Working of, and in the Conversion of Taper-Bar Presses into. G. E. Selby, Hull. Eng. Pat. 8823, April 26, 1895.

STRUCTURAL alterations are proposed and claimed of such a kind, that besides the conversion foreshadowed in the title, in the working it is stated, greater cleanliness is secured, general construction is simplified, and increased economy effected.—J. J. K.

Soap, Tormentil, An Improved Process for making, by the Cold Process. W. P. Thompson, Liverpool. Eng. Pat. 8814, May 3, 1895. From J. B. Okie, Wörishofen, Germany.

CAUSTIC soda-lye is run into cocoa-nut oil with stirring, and there is added to the mass a mixture of extract of tormentil, tincture of tormentil, sassafras oil, sandal-wood oil, oil of fennel, and oil of violets. The extract of tormentil imparts to the soap a bluish-brown tint.—J. J. K.

Separating Oleaginous Matter from a Solvent, Apparatus for. J. F. Lester and A. Riccio, Atlanta, Georgia, U.S.A. Eng. Pat. 23,159, Dec. 3, 1895.

THIS is an apparatus designed for the purpose of separating oils or fats from the hydrocarbon solvent used in their extraction from seeds or animal matter, without the aid of heat. The still employed is placed inside a closed vessel filled with cold water, in which is a coil for condensing the vaporised solvent, as it is withdrawn by means of a vacuum pump. The novel feature consists in the principle that when a vacuum is formed in the still, the solvent rapidly vaporises, and, on being pumped into the condenser, the latent heat which it contains passes into the water, becoming sensible heat, which then warms the oil in the still, thus assisting the distillation, until the whole of the solvent has been vaporised and condensed.

—J. J. K.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A).—PIGMENTS, PAINTS.

Bronze-Colour Manufacture, Developments in. E. Odenheimer. *Dingl. polyt. J.* 1896, 299, 43–48.

IN this manufacture, thin hammered brass leaf is reduced to metallic dust, after which it is graded as to size. For the coarser kind of powders the material is subjected in the polishing mill to the action of steel wire brushes rubbing against the steel walls of a closed cylinder, a small proportion of fatty matter being added to prevent oxidation. To reduce to still finer condition, the powder is commonly rubbed with gum-arabic solution, and washed and dried at the lowest possible temperature. Oxygen, moist carbon dioxide, and hydrogen sulphide tarnish the powdered metal. Rosenthal, in 1893, endeavoured to avoid the tarnishing by these gases in the air, by conducting the operations either in a vacuum chamber, or in one supplied with air, from which oxygen and harmful gases had been absorbed. When a vacuum is used, an electro-motor forms a convenient driving agent for the rotating mechanism, as it may be itself enclosed within the exhausted chamber, and obviates the necessity for packing a rotating joint, airtight. Siebelstiel, in 1894, patented a pattern of stamp by which the agglomeration of bronze particles in places where they are but little rubbed, is prevented (Ger. Pat. 81,420, 1894). Sattler (Ger. Pat. 61,069, 1891) combines a grinding mill, in which roughened steel balls rub against hard steel ribs, with a polishing mill, in the same apparatus.

The Colouring of Bronze-Powder.—The powder is heated in open vessels with oil and vinegar, or with wax, paraffin, or oils containing sulphur; or (by Buchner's process) by shaking in a closed vessel with hydrogen sulphide solution, letting stand for 24 hours, drying, and heating in an oil-bath until sufficiently coloured; or by the fumes of ammonium sulphide; or by heating (brass) in stannous chloride solution. Zinc-dust is frequently coated with brass by simple immersion in a copper and zinc cyanide solution, the powder being kept in agitation by means of brushes (see this Journal, 1894, 13, 893 and 958); it is then treated finally in the usual polishing mill. Copper is best obtained for use as bronze-powder by the reduction of finely-ground copper oxide in hydrocarbon vapours.

Bismuth-Aluminium Bronze-Powder.—Lehmann (Ger. Pat. 14,242, 1887) prepares bronze-powder from an alloy containing 5 to 10 per cent. of Al, and 0.05 to 0.1 per cent. of bismuth. The filings of this are heated, crushed under stamps, the powder again heated, rubbed, sifted, and polished between rolls. The shade of colour is altered by varying the percentage of aluminium, and by heating in air.

Improvements in Bronzing Apparatus.—Supf has patented a process of direct printing in bronze (Ger. Pat. 74,452 and 74,453, 1893). The bronze is washed by means of hypochlorite of soda (eau de Javelle), and in polishing, a small quantity of refined glycerin is added; the powder is then mixed with dissolved albumin and glycerin, and finally ground with gum-solution, beer, and carbolic solution to a suitable paste. For printing on felt-like materials, the colour is mixed in the necessary proportion with 1,500 grms. of dammar and 1,600 grms. of boiled linseed oil. Blancan (Ger. Pat. 73,267, 1892) has also patented a direct-printing bronze, by mixing aluminium-bronze powder with a solution of shellac in borax water, with the addition of oxgalls to render the paint supple after drying. For "liquid bronzes," the action of the fluid medium upon the metal must be avoided. Stroschein (Ger. Pat. 52,973, 1889) accomplishes this by dissolving dammar in benzene and neutralising any acidity with ammonia before mixing the bronze-powder with it. Ferl (see this Journal, 1894, 13, 164) uses a solution of pyroxilin in acetic ether or amyl acetate. Menrer (Ger. Pat. 76,220, 1891) coats metal surfaces with aluminium by sprinkling the powdered material upon a half-dry film of tar painted upon them; the object is then heated to 300°–350°C. in a muffle, when the varnish melts, and the aluminium forms a smooth, bright surface that is readily cleaned by washing.

Bronze Substitutes.—Mosaic gold was one of the chief of these, and is still used almost universally for treating lamp stems, as bronze-powders are ruined by the acidity of the varnish employed. Coloured mica bronzes are now made by Sachs, Meyer, and Gerstendorffer, of New York (this Journal, 1894, 13, 532). They are now, however, displaced by tin bronzes coloured with coal-tar dyes. The mica bronzes were obtained by crushing the material in stamps, boiling with hydrochloric acid to remove traces of iron, washing well, and sifting. The powder was used white, or tinted with aniline colours. To colour the mica powder, the New York firm treat it with dilute solution of white of egg, dry it, and after steaming, place it in the colour vat; bronze powder is mixed with it to increase the lustre. Silver and gold are cheaply obtained in powder by painting a mixture of one of their salts with gum senegal upon a glass plate and placing it in an atmosphere of hydrogen phosphide; after drying, the coating may be washed off the plate and pulverised. Lead and tin give metal-like powder, by treating their salts with hydrogen sulphide after the same manner.—W. G. M.

PATENT.

Paper, Wood, Metals, Canvases, and other Materials. Improvements relating to Ornamenting, Printing, and Writing on. H. Thacker, London. Eng. Pat. 6938, April 4, 1895.

ANY kind of plain, tinted, or coloured writing paper is covered wholly or partly by a solution of colouring matter made from aniline or other chemical material (with, in some cases, the addition of a mordant, to prevent it from being washed out), which can only be discharged by means of acids, alkalis, or other chemicals. The paper is then written upon, stamped, or printed with a chemical fluid or ink, composed of a solution of calcium hypochlorite in distilled water with the addition of a little acetic acid. The action of this ink leaves the parts, which have been impressed with it, bare, thus exposing the colour of the under surface of the paper. Combination colours can also be used. The process is said to be suitable for the manufacture of cheques and bankers' drafts to prevent forgery and alterations.—J. J. K.

Waterproof Coating Compositions for Wearing Apparel, Covers, Engine and other Packings, Acid Tank Linings, and for other Uses, Improvements in the Manufacture of. C. J. Grist, London. Eng. Pat. 21,742, Nov. 15, 1895.

LINSEED oil is boiled with litharge for 24 hours at 400° F., the mixture being kept in motion during this time and for a further 24 hours, after which the oil is allowed to cool to its normal temperature. Any fibrous substance, such as jute, hemp, and cotton, after carding to free it from deleterious foreign matter, and drying to expel all moisture,

are immersed in a loosened and graduated condition in the oil, and immediately taken out again, when they are placed in a hydro-extractor to extract the superfluous oil. The fibre is now spread loosely on wire gauze, and a current of heated air blown through it till each particle of adhering oil has been oxidised and dried. The operation of dipping and oxidising is repeated twice. The fibre is then ground into a homogeneous condition, and placed in crushing rolls with the addition of 5 per cent. to 10 per cent. of powdered sulphur; after being thoroughly mixed it is allowed to cool, replaced in the rolls, and any desired colouring matter added. It is then ready for waterproofing goods.—J. J. K.

Oil [For Finishing Wood], and of a Varnish Prepared therefrom, Improvements in the Manufacture of. L. Knoche, Hamm, Germany. Eng. Pat. 24,224, Dec. 18, 1895.

200 lb. of oil pressed from the berries of a tree called "Abura Giri" or "Japanese wood oil," are boiled until a temperature of 205° C. is reached, and maintained at this temperature for three hours to render the oil of greater density. It is then cooled down to 180° C., and 70 lb. of naphtha or turpentine are thoroughly mixed with the oil to cause it to flow freely. Linseed oil may also be mixed with the raw oil and treated in the same manner. The oil compound produced is said to be superior and more durable than either linseed or cotton seed oils. A mixture of equal parts of this oil compound and ordinary varnish is said to produce a new varnish, which is superior in finish and brilliancy.—J. J. K.

Water for Tanneries, Valuation of. A. Bartel. Dingler's polyt. Jour. 1896, 299, 136—141.

THE waters A, B, C, and D (see table) were found by Simand (Gerber, 1889, 15, No. 361) to be good for the purposes of a tannery, whilst E was very unfavourable, both on account of its high content of carbonates and its excess of chlorides. In this water (E) sole-leather hides plumped very badly and were difficult to tan. The water B plumped the hides quickly and tannage was comparatively rapid. A left the hides somewhat softer in the suspenders, a result

which Simand attributes to the higher temperature of this water than that of B, which it closely resembles in other respects.

Water No. 20 is very soft, but contains much organic matter besides that held in suspension (0.7 mgrm. per litre). In such a case filtration of the water through spent bark, and provision for keeping the soaks as cool as possible, should be resorted to.

Nos. 21 and 22 suffer from excessive hardness, and gave very poor results, probably due to over-plumping and con-

traction of the grain, slow tannage and hard leather being the main faults. No. 23 produced a leather showing black specks, which the tanner attributed to the iron, but which were more probably due to organic lime salts or putrefactive bacteria, for the water was comparatively rich in organic matter.

In the case of several of the waters here given the practical results are at variance with those which would be expected from our knowledge of the effect of the presence or absence of this or that salt on the hide. Thus with water No. 4 an excellent oak-tanned sole leather is made, in spite of its extreme softness and poverty in sulphates. The same may be said of No. 11, whilst the abnormal hardness of No. 15 and the excess of alkali sulphates in No. 17 do not prevent the production of a mild upper leather, so that these waters cannot be supposed to cause excessive plumping. The high content of iron in

Nos. 5 and 16 does not seem to have any prejudicial effect on the colour of the finished leather, since no complaints have been made in this respect. Particularly remarkable is the fact that a good product is sent out from the factories using waters Nos. 13 and 14, which the majority of experts would certainly condemn for tannery use.

The author concludes that whilst it must be admitted that the separate constituents of a water, together with its physical properties, have a weighty effect on the individual operations of the tannery, there is no doubt that every water, save mineral waters and sea water, may be employed by the tanner. It must not, however, be forgotten that in the majority of cases, it is essential that the tanner should have an intimate knowledge of the properties of his water, and should arrange his practice in such a way that these shall not prove injurious.

Tanning and Preparing Leather, Manufacture of a New Acid and Glycerin, or Acid, Glycerin, and Alcohol Mixture, and its Application for. M. Schmeltzer and C. Aschman, Ettelbruck, Luxemburg. Eng. Pat. 7365, April 10, 1895.

In order to "swill" hides in an acid bath, so as to obtain leather which is supple and not liable to crack in bending, a liquor is used which is prepared as follows:—3.5 parts of crude methylated spirit are mixed with 4 parts of crude glycerin, and 15 parts of sulphuric acid (60° Beaumé) are added while constantly stirring. When this mixture has cooled it is added to water in the proportion of 7 litres to 5,000 litres of water. For thick and fresh hides and for trans-atlantic dry hides the proportion of glycerin is increased. The mixture of methylated spirit, glycerin, and sulphuric acid is to be known as "Malattinic acid."

Tannic Extracts, An Improved Process for Decolorising and Clarifying. A. Sinan, H. Sinan, and E. Gouin, Nantes, France. Eng. Pat. 7555, April 13, 1895.

The ooze is led from the diffusion vat to a vat provided with a steam-coil, and the liquor heated to boiling. During the heating, residues from grain or oleaginous fruits which have been pressed for their oil, are added and are mashed in the ooze for about an hour. The quantity of residues used is regulated by the degree of decolorisation to be effected; 500 grms. per 100 litres per degree Beaumé are recommended. The liquor is allowed to cool, filtered, and concentrated in a vacuum.—A. G. B.

XVI.—SUGAR, STARCH, GUM, Etc.

Sugar Industry, Progress in, for the last Quarter of 1895. Dingler's Polyt. J. 1896, 299, 91—95.

Reducing Power of Levulose.—R. Lehman has constructed tables for the gravimetric estimation of levulose, and for

this purpose used a syrup containing 83.14 per cent. of the sugar prepared from inulin by the action of 0.5 per cent. sulphuric acid. O. Sule (this Journal, 1895, 498) employed pure crystalline levulose, and has shown that more copper is obtained when Lehman's method is followed than that author's tables will account for. With very dilute solutions the results are fairly concordant, but with greater concentrations differences of more than 20 mgrms. occur. These divergences induced Sule to revise Lehman's tables from 20 to 130 mgrms. of copper.

The Occurrence, Properties, and Action of the Caramel Constituents of Cane-Sugar (Raw Sugar).—C. Volmer's investigations on this subject were carried out in 1883, and have recently been published (*Zeits. des Ver. f. die Rüben-zuckerind. des deutsch. Reich.* 1895, 45, 451). They were made to afford explanation of the damage done to the boiler, the seams of which were loosened, whilst the boiler plates were caused to bulge considerably and showed deep corrosion, the interior of the boiler being covered with a layer 50 to 60 mm. (the bottom plates 300 mm.) thick, of a substance bearing a resemblance to peat. In the main steam-pipe were found large masses of a stiff blackish-brown matter which exuded from the joints in the form of glistening stalactites. These substances are shown to be the decomposition products of cane-sugar.—Caramelan, Caramelen, Caramelin—and under the combined influence of steam pressure and metals, metallic oxides in particular, assume a form characteristic of their chemical individuality. By special experiments the author has demonstrated that the presence of metals exerts an accelerating influence upon the decomposition of sugar, and that at the commencement of decomposition rapid oxidation of the metal takes place from the combined action of the nascent elements of water, and the resulting acid caramel components. Considerable quantities of the metal forming the boiler walls are removed, their superficial corrosion being thus accounted for. It, therefore, appears that the decomposition products of sugar are of a nature to cause considerable harm when chemical change is in progress within the apparatus employed for the generation of steam.

The Mucilage Separated in the Osmose Process and the Dextrans resulting therefrom.—According to Anderlik (*Zeits. f. Zuckerind. in Böhmen*, 1895, 20, 81) this mucilage is caused by certain bacteria. The fresh substance consists of closely grouped colonies of micro-organisms apparently connected to one another by secreted unorganised matter. The first coloration of the mud appears at a later stage of the decomposition, and is not due to the molasses, provided that the inflowing liquid is exclusively diluted osmose water. The inflow, at first alkaline, becomes acid in the presence of the mucilage and reduces Fehling's solution. In the event of much mud accumulating in the osmogen and reaching the osmose water stored in the reservoirs, the latter may become acid, and the sugar it contains is consequently inverted. In conjunction with infection the following are the necessary conditions for the production of the mud:—a steady introduction of osmose water drop by drop, sufficient air, a temperature of 18° to 30° R., and a uniform outflow.

The formation of the mucilage takes place for the most part at the expense of the cane-sugar, which is primarily converted into dextrose and levulose. The glucose is used up as a plastic material for the formation of the bacterial cells, whilst the levulose undergoes further decomposition. It appears that less solid matter and matter soluble in water is contained in the newly-formed mucilage than in the old. The soluble matter is the product of the decomposition of the mucilage caused by various processes of fermentation which are accompanied by the formation of fatty acids and, in particular, of lactic acid; moreover, a portion of the insoluble solid matter becomes soluble by the action of enzymes resulting from the fermentation, since, if the mucilage is filtered, the filtrate contains a dextran which undoubtedly is a hydrolytic product of the insoluble slimy substance. An old mucilage, when treated with alkalis, emits an odour of ammonia and methylamine.

The author has extended his investigations on the hydrolysis of the mucilage, and has ascertained that the portion of the slime insoluble in water is a hemicellulose, for when hydrolysed it forms substances which vary according to the

intensity of the hydrolysis. The products are dextrose, dextrans, and substances intermediate between these and the former. The dextrans may be divided into two principal groups, A. and B., according to their behaviour towards basic lead acetate. A. is composed of the precipitable, B. the non-precipitable dextrans. In A. are included two characteristic types, neither of which reduces Fehling's solution. The aqueous solution of the first type is strongly opalescent, and has a low specific rotation, whilst that of the second type is not opalescent, and has a greater rotation. Group B. is not of a pronounced dextran character; its rotatory power is less than that of the first group, and it reduces Fehling's solution.

N. Rydlewsky (*Die deutsch. Zuckerind.* 1895, 20, 1411) has studied "The Ash of Beetroot Slicings dried according to the Büttner-Meyer Method." It has been found that the chemical composition of slicings is practically unaltered by drying; the ash-content, however, increases from the adhering dust. Inasmuch as the percentage of ash in the dried slicings varies according to different authorities, the author has examined the beetroot material of the last three campaigns for the elucidation of this question. From his results he finds that the slicings undergo no chemical alteration on drying, but the ash-content increases to about 1 per cent., calculated on the dry substance, on account of ash from adhering dust. This latter contained from 10 to 15 per cent. of lime, and so explains the increase of lime (0.68 per cent.) in the ash of the dried slicings. The percentage of sulphuric acid in the dried slicings was raised to 0.93 per cent. on the dry substance, in consequence of the oxidation of the sulphurous acid in the furnace-gas. In some factories the high-pressure revolving presses as constructed by Büttner and Meyer are in use, and since in this process lime is added to the pressed slicings, some samples were examined for the purpose of comparing them with the unlined slicings. It was found that the dry lined slicings contained more ash, and that the amount of calcium oxide had increased by 2.68 per cent. on the dry substance as compared with that in the unlined slicings.—J. L. B.

Extraction, Estimation of, in Sugar Houses. M. Trubek. *J. Amer. Chem. Soc.* 1895, 17, 920—923.

In 1865, E. Lecry (*Ann. chim. et Phys.* 5, 350—410) determined the extraction of the cane (the weight of juice obtained from 100 parts of cane) by quickly digesting a known weight of bagasse with warm water, drying perfectly in an oven, and weighing, the fibre of the cane being previously known. In order to effect a more thorough exhaustion of the sucrose in the cane, water is allowed to run in fine streams over the bagasse as it comes from the first set of rollers; the resulting bagasse contains therefore a certain amount of water which does not belong to the cane. In such a case the author determines the extraction in the following manner:—

F_{100} = Fibre in diluted bagasse.

B = Original bagasse corresponding to 100 parts of diluted bagasse.

F_c = Fibre in cane.

x = Bagasse resulting from 100 parts of cane.

E = Extraction.

$$1. \quad \frac{F_{100} \cdot 100}{B} : F_c = 100 : x$$

$$2. \quad 100 - x = E$$

The unknown figures are B , x , and E , as F_{100} and F_c are found by analysis of the cane and of its bagasse. To find a third equation, the sucrose in the cane S_c in the extracted juice S_p , and in the resulting diluted bagasse S_{100} are determined. In $(100 - E)$ bagasse there is left $(S - \frac{ES_1}{100})$ sucrose,

or in 100 bagasse $(S - \frac{ES_1}{100}) \cdot 100$. The third equation is:

$$3. \quad \frac{(S - \frac{ES_1}{100}) \cdot 100}{100 - E} = \frac{100 S_{100}}{B}$$

After eliminating we have—

$$E = \frac{a}{2} \pm \sqrt{b + \left(\frac{a}{2}\right)^2}, \text{ where}$$

$$a = \frac{100 F_{n1}(S + S_1) - 100 S_{n1}F_1}{S_1 F_{n1}}$$

$$b = \frac{10000(F_{n1} - F_1S)}{S_1 F_{n1}}$$

—J. L. B.

Raw Sugar, Grey Colour of. Herzfeld. Zeits. Rübenz. Ind. 1896, 46, 1.

A SERIES of experiments show that grey or reddish-grey sugars as a class have an acid reaction towards phenolphthalein, and that this discoloration of the products is no longer observed when their manufacture is so conducted that they have an alkaline reaction. The author observed that certain sugar factories working with the so-called dry defecation, i.e., defecation with caustic lime, obtained unsatisfactory results. The alkalinity of the solid products was not estimated, whilst that of the syrups was determined with rosolic acid as indicator, the use of which led to great errors, for the apparently alkaline juice was in reality acid, and therefore readily dissolved ferric and ferrous oxides, in the presence of which (during the process of saturation with sulphurous acid) discoloured sugars result. By proper methods of controlling the manufacture, the formation of grey sugar may be avoided, and in the event of harm having already occurred, it may be minimised by subsequently covering the sugar with a strongly alkaline syrup.—J. L. B.

PATENTS.

Sugar, Improvements relating to the Separation of, from Sacchariferous Solutions, Juices of Plants, and the Like. Haseltine and Lake, London. From G. Kassner, Munster, Germany. Eng. Pat. 23,171, Dec. 3, 1895.

CANE or other varieties of sugar can be separated from their solutions by treatment with hydrated or non-hydrated oxide of lead. The oxide of lead is mixed with substances which are without chemical action on sugar, such as fibrous cellulose, carbonate of magnesium, saccharate of lead, &c. The mixture, which may be prepared beforehand, is employed in a moist pulpy condition or in the form of a solid resistant material, the latter being formed from the pulp by exposure to air, or to heat, and partial vacuum. Such mixtures are suspended in the solution of sugar and allowed to stand, or the solution may be filtered through the mixture, or these methods may be combined. The separated lead saccharate is afterwards treated with carbonic acid, or a gas containing carbonic acid.—J. L. B.

Potato Starch, Process for Treatment of, with Chlorine and Heat. Abel and Inray, London. From C. Hellfrisch, Kyritz, Prussia. Eng. Pat. 24,456, Dec. 20, 1895.

The inventor describes two processes for removing the unpleasant flavour and odour of potato starch.

In the first method the potato starch coming from the rasping machines and diluted with water is conveyed into a preliminary heating apparatus provided with stirrers. The contents are then raised to about 45° C., treated for a short time with chlorine, chlorinated water, or chloride of lime solution, and washed in the usual way.

In the second method a very thin paste of the raw potato starch is heated in suitable vessels fitted with stirrers to a temperature of 45° C., and then treated with a chlorine solution as above described. 1,000 kilos. of starch liquid, containing 1 part of starch to 1.5 of water, require 200 to 300 litres of a 0.2 to 0.25 per cent. solution of chlorine.—J. L. B.

XVII.—BREWING, WINES, SPIRITS, Etc.

Fermentation-Limit of Different Potatoes, Variations in. G. Heinzelmann. Zeits. Spiritus ind. 1896, 19, 33.

GREAT variations are observed in the fermentation-limit of potatoes, which appear to be traceable to differences in the climate, soil, and manures, as well as to the degree of ripeness of the potato. Unripe potatoes give the worst results; and in one case where they were taken whilst the plant was still in bloom, the fermentation limit was reached at 6—7 B., and the addition of 150 lb. of malt to the vat only brought it to 4 B. "Daber" potatoes with the same yeast and malt, and under like conditions always reached the limit at 1.2 B.—W. G. M.

Di-Saccharides, Can they be rendered Fermentable by the Presence of a Fermentable Sugar? H. Van Laer. Bull. Assoc. Belge d. Chim. 9, 319—322.

THE monosaccharides vary in point of susceptibility to the action of ferments, only those sugars not far removed from glucose in geometric molecular arrangement being decomposable by these organisms. In the case of the di-saccharides the conditions are different, the preliminary hydrolysis of each sugar into the corresponding monose by the action of a special enzyme being an essential prelude to fermentation.

In view of the results obtained by Bourquelot revealing the possibility of an ordinarily non-fermentable monosaccharide, such as galactose, being fermented when associated with a readily fermentable sugar like glucose, the author experimented on the same lines with disaccharides to see if they too were capable of being rendered fermentable by a similar process of induction. Such an effect, if occurring, would dissipate the current theory on the necessity of special enzymes to produce hydrolysis, but the results of the investigations made under varying circumstances with two torule, one incapable of fermenting maltose, and the other capable of fermenting saccharose but not maltose when unmixed with other sugars, show that the fermentation of those disaccharides cannot be brought about by the presence of readily fermentable sugars.—C. Malt, Improvements in Apparatus or Machinery for the Manufacture or Production of. A. Ravinet, Dunkirk, France. Eng. Pat. 3480, Feb. 18, 1895.

THE operation of malting is effected in the following manner:—The damp grains are introduced at a at the upper part of the enamelled or galvanized iron cylinder A, which is not completely filled, so as to allow of germination and swelling. The cylinder is then revolved. The suction pipe D¹ and the aperture U are opened; the register V is closed. The sprayer p is started and so regulated that the entering air is saturated with aqueous vapour. At the ends of the cylinder are screens W, upon movable axes W¹, and the former have a tubular piece X, the cylindrical parts of which coincide with the arrival and exit pipes D D¹. The terminal head Z of the screen W is situated at the lower part of the conical end B; the tubular piece X serves as a counterweight to the screen W, which consequently always remains uppermost, and the gases can only penetrate the grain at the lower part of the cylinder.

During the rotation of the cylinder A the grains roll on to the metallic gauze webs G, which prevent the packing and agglomeration of the grains by a constant change of their position. The metallic gauze only extends to within a certain distance from the side of the cylinder and the

space Q thus formed, allows the grain to pass from one section to another.

When the grain is sufficiently germinated, the sprayer *p* is stopped and the door *U* of the pipe *P* closed. The hot current of air from *R* is put into communication with the cylinder *A* by opening the register *V* as well as *Q* communicating with the fan.—J. L. B.

Malt, Improvements in or connected with Manufacture of, and in Malt Houses for Treating Same. F. Colley, Tadcaster. Eng. Pat. 5329, March 13, 1895.

AFTER the grain has been soaked, it is removed from the tank and vegetated on the growing floor until it reaches a perforated floor, over which it is distributed by means of fans. These fans draw in hot or cool air, and force it into a space beneath the floor, of a sufficiently large size to allow the temperature of the air to become equalised, and to make it rise at a regular rate through the perforated floor. The grain is treated with the forced draught until it is dry enough for removal to the kiln. It is claimed that the malt is withered more effectually, and time economised in which the malt remains on the kiln. A larger output follows; for when the kiln is not required for its especial purpose, it may be employed for drying barley previous to storing.—J. L. B.

Malt and Grain, Improved Method of Treating, in Brewing and other Operations. Harris and Mills, London. From P. Puvrez, Lille, France. Eng. Pat. 5780, March 19, 1895.

DURING the process of mashing the malt and grain, either whole or crushed, is submitted to a wet grinding. For this purpose, the entire mash is passed between plane or roughened rollers of metal or porcelain, placed very close to each other. The rollers can be fixed on the edge of the brewing vat, or in any other desired position, and may be heated internally by steam or water to avoid lowering the temperature of the mash, or to raise it if necessary. By this treatment the kernel of the grain is reduced to a paste, and the husk left intact for the effective filtration of the wort.—J. L. B.

Sterilising Liquids, Improvements in and Apparatus for. E. W. Kuhn, Paris. Eng. Pat. 7286, April 9, 1895.

THE sterilisation by heat of liquids, especially fermented liquids, has not hitherto been generally successful, owing to the undesirable chemical and other changes frequently resulting from the treatment. The inventor's object is to provide an apparatus in which these changes may be prevented or reduced to a minimum (1) by conducting the operation in a closed vessel, kept in oscillatory movement, and provided with such a large heating surface that the necessary temperature may be attained very rapidly and without local overheating; (2) by rapid artificial cooling of the liquid as soon as complete sterilisation has been effected; and (3) by coating the interior of the vessel with silver, so

that the liquid may be kept from contact with metals likely to produce chemical effects. Such an apparatus is described in the specification.—L. A.

Alcoholic Liquors, An Improved Method of and Apparatus for Purifying and Refining. D. Young, London. From C. Ballock, Cambridge, U.S.A.; and C. M. Reed, Boston, U.S.A. Eng. Pat. 24,387, Dec. 19, 1895.

SMALL quantities of the alcoholic liquor, in the form of a shower or spray, are delivered from a distributor into a tank. They are here subjected to the action of air which has previously been passed through hot water, whereby fusel oil and other impurities are oxidised. The air, freed from alcoholic vapours, accumulates in a condensing-chamber until the pressure is sufficient to open a safety-valve.

—J. L. B.

Casks, Barrels, or the like, Improvements in or relating to Apparatus for removing Pitch from. A. J. Boulton, London. From C. F. L. Froberg, Rosswein, Germany. Eng. Pat. 1412, Jan. 20, 1896.

THIS is a process for cleansing barrels from pitch by passing superheated steam through a nozzle of special construction, which fits tightly into the tap-hole of the barrel. The melted pitch and exhaust steam find their exit through the bung-hole.—J. L. B.

XVIII.—FOODS; SANITATION, WATER PURIFICATION, & DISINFECTANTS.

(A).—FOODS.

Oil-Cakes and other Feeding-Staffs, Free Fatty Acids in. B. Dyer and J. F. H. Gilbard. Analyst, 20, 241.

THE authors give the results of the examination of nearly 1,000 oil-cakes and feeding-stuffs of different kinds (this Journal, 1893, 8). In newly-made cakes, the amount of free acid was generally very small. In 116 samples of freshly-made cakes the free acid only amounted to about 3 per cent. of the oil, and in over 100 samples the amount did not exceed 5 per cent. of the oil. In 11 samples the free acid was between 5 and 10 per cent. of the oil, whilst in two samples it was between 10 and 12 per cent.

Out of 268 linseed cakes made from well-screened linseed, 170 samples contained free acid not exceeding 5 per cent. of the total oil, while 69 samples contained free acid amounting to between 5 and 10 per cent. In 14 samples the free acid amounted to between 10 and 15 per cent., in 15 others, from 15 to 20 per cent., and in 10 samples above 20 per cent. of the oil.

71 cakes made from impure linseed gave an average acidity of over 15 per cent. of the oil, 21 of the cakes having over 20 per cent. of free acid.

"Dirty," impure cakes generally show higher acidity than pure cakes, and high acidity in pure cakes generally shows that they are in bad condition. The free fatty acid is given in terms of oleic acid, obtained by multiplying the quantity of potash used to neutralise the oil by 5.

A table is given showing the results obtained with rape seed, ground-nut, maize, rice meal, &c.—A. S.

PATENTS.

Food, A New or Improved, and Method of Manufacturing the Same. W. P. Thompson, Liverpool and London. From L. H. Green, Durban, Natal. Eng. Pat. 2909, Feb. 9, 1895.

THE new red-coloured grain, of Kaffir corn or mealies, is first thoroughly washed, the skimmed off floating particles being useful as a food for fowls. After soaking for 24 hours in soft water, the grain is placed in sacks in a warm place and kept until it begins to germinate, which it will generally do in 12 hours. It is now dried and then roasted like coffee in a revolving cylinder. The grain is then cleaned in a stamping mill, or otherwise. The outer skin is now removed from the kernel, and the latter is then ground in a roller mill to the required fineness. The meal may be advantageously mixed with half its weight of ordinary baked flour. To 50 lb. of this mixture may further be added 3 oz. of a preparation of 2 parts of table salt and 1 part of bicarbonate of potash, and the whole is then baked in an oven and well stirred. The product will keep for a long time in tins or other air-tight packages, and is devoid of the ill-flavour of the untreated Kaffir corn.—L. de K.

Eggs, An Improved Process of Preserving. E. Markham, London. Eng. Pat. 3513, Feb. 18, 1895.

THE preserving liquid is made by dissolving $7\frac{1}{2}$ oz. of boric acid, 1 oz. of borax, and 2 oz. of cornflour in a gallon of water and boiling for 3 minutes. If the water is very hard it is advisable to add $\frac{1}{4}$ oz. of soda. To improve the taste $\frac{1}{2}$ oz. of best sugar may also be added. As soon as the solution has cooled down to 204° – 210° F., the new-laid eggs supported on an openwork galvanised iron tray are dipped in the liquid for 11 seconds, the tray being kept in motion during that time. The eggs are then allowed to dry in a suitable receptacle, so as not to touch one another. When dry, they are made to stand on their longer ends in suitable cases and sprinkled over with boric acid. They may then be kept for a long period in a cool dry chamber.—L. de K.

Bean Flour, Improvements in the Manufacture of. H. H. Lake, London. Communicated by A. D. Bergtold and I. H. Falk, both of New York, U.S.A. Eng. Pat. 19,832, Oct. 22, 1895.

THE object of the inventors is to deprive beans of their disagreeable taste without removing any valuable constituents.

A batch of ordinary dry beans is reduced in a suitable grinding machine to the size of split peas, and the mass is then introduced into a tank containing a solution of 5 parts of soda and 95 parts of water and left to soak for 24 hours with frequent stirring. The alkali loosens the hulls from the beans and also dissolves the undesirable albuminoids. A little of the gluten-fibrin is also dissolved, but not in sufficient quantity to reduce the nutritive value. The detached hulls rise to the surface of the liquid and are skimmed off, whilst the heavier bean substance settles to the bottom. The alkaline liquid is drawn off and the beans are then removed to another tank containing a mixture of 1 part of hydrochloric acid and 99 parts of water, to neutralise the alkali. The excess of acid is then removed by washing by means of spray pipes arranged in the upper portion of the tank, the water escaping through an outlet pipe provided with a strainer. The mass is then dried in a suitable apparatus at a temperature not exceeding 215° F., and is then reduced to flour in a suitable grinding mill.

The dissolved albuminoids may be recovered by neutralising the fluid and may be used as cattle food or manure.—L. de K.

Nitrogenised Water, An Improved Process of Manufacture of. H. J. Haddan, London. From E. Freixa, Barcelona, Spain. Eng. Pat. 24,293, Dec. 18, 1895.

Air, deprived of oxygen by the combustion of phosphorus in the inverted bell of a hydro-pneumatic apparatus, is taken through washers containing solution of caustic soda, and is then pumped into a tank containing water, from which suction pipes simultaneously draw the water and gas to an air-compressor, in which they are subjected to a pressure of 18 atmospheres, while being agitated, to produce nitrogenised water.—E. S.

(B.)—SANITATION: WATER PURIFICATION.

PATENTS.

Precipitation Tanks for the Clarification of Sewage and Impure Waters, Improvements in or relating to. J. S. Pickering, Nuneaton, Warwick. Eng. Pat. 4186, Feb. 27, 1895.

UPWARD-flow precipitation tanks, provided with means for the removal of sludge, are furnished with filter-beds supported on fixed floors carried by girders which are built into the upper sides of the tanks. The filter beds, which are formed of gravel in the ordinary manner, are flushed periodically by removing the sludge from the tank below.—L. A.

Purifying Water, An Improved Method of. T. Royle, London. Eng. Pat. 8256, April 26, 1895.

THE purification of water for drinking purposes is effected by first mixing it with a solution of an alkaline manganate or permanganate and then with a solution of manganous chloride or other manganous salt. The precipitate is removed by filtration. Quantities mentioned are 1 grain of potassium permanganate and 2 grains of manganous chloride per gallon of water. If it is desired also to soften the water, the necessary quantity of lime is added during or at the end of the purifying treatment.—L. A.

Furnaces suitable for Consuming House, Trade, and other Refuse, Improvements in. J. B. Allott and J. McC. C. Paton, Nottingham. Eng. Pat. 8748, May 2, 1895.

THE furnace consists of a main combustion chamber, having a hearth and fire-grate at the bottom, a feeding opening at the hearth end, and a clinkering door at the grate end; this chamber has an arched reverberatory roof, through which pass ducts to flues or supplementary combustion chambers located above the roof of the main chamber. By this arrangement all gases and products of combustion have to pass over the hottest part of the fire before entering the flues or supplementary combustion chambers, and in these flues complete oxidation may be ensured by the admission of a secondary air supply.—A. G. B.

Purifying Water in Reservoirs and the like, and in Steam Boilers, An Improved Composition for. L. Lachery, La Bassée, Department du Nord, France. Eng. Pat. 11,289, June 8, 1895.

THIS composition contains "distilled water, eachon (an extract obtained from the *mimosa catechu*), neutral oxalate of potash, oxalic acid mixed with organic substance, neutral phosphate of soda, sugar, tannin, molasses, glycerin, potato flour, caramel, and pure crystallised nitrate of silver."—L. A.

(C.)—DISINFECTANTS.

Protecting Sugar Canes, Grape Vines, Currant Bushes, and like Plants from the Attacks of Parasites or Injurious Insects or Vegetable Growths, A New or Improved Preparation for. J. Y. Johnson, London. Communicated by A. Figge, Hameln, Germany. Eng. Pat. 6313, March 27, 1895.

NATURAL bitumen, reduced to a sufficiently low temperature to make it hard and brittle, is finely ground, and then intimately mixed with powdered dry clay, chalk, or earthy material in order to prevent the particles of bitumen from

adhering together or to the roots of the plants in such a manner as to injure them. This mixture, called "Strabonite," is to be introduced into the soil in which the plants are grown.—L. A.

Sulphurous Acid for Curative Purposes. An Improved Process for Manufacturing a Solution containing. F. Hartmann, Hallein, Austria. Eng. Pat. 19,702, Oct. 19, 1895.

THE aromatic parts of plants rich in essential oils, such as the pine, spruce fir, eucalyptus, peppermint, juniper, &c., are distilled in a digester with a solution of alkaline or alkaline-earthly bisulphites, under a pressure higher than the atmospheric. The distillate, which is an amber-yellow liquid of fragrant odour, is said to contain sulphurous acid in a form which does not irritate the respiratory organs and yet is fully as effective antiseptically as pure sulphurous acid. For curative purposes, the distilled liquid is caused to drip on to pine branches or shavings arranged in suitable frames, and the air thus impregnated with the vapours is inhaled.—L. A.

Disinfection, Formaldehyde Lamp for. B. Tollens. Zeits. f. angew. Chem. 1896, 51.

THIS is a spirit lamp with a hood of platinum wire gauze. The lamp is filled with wood spirit of about sp. gr. 0.792, and the hood placed over the wick, resting on the flat part of the wick-holder. A light is applied and as soon as the flame completely envelopes the hood, it is

extinguished by a momentary use of the glass cap. The platinum continues to glow, and formaldehyde is abundantly evolved. The chimney is now placed in position and the air-supply regulated so that the platinum glows brightly but no flame appears.—A. C. W.

Oxalic Acid, Behaviour of, during Putrefaction. D. Vitali. Boll. chim. farm. 1895, 34, 641.

100 grms. of flesh cut into small pieces, and some albumin were placed in a flask containing 2 grms. of oxalic acid dissolved in 1000 c.c. of water and allowed to stand for nine months. During this period the temperature was most favourable for putrefaction: in the summer it fluctuated from 25°–30°. At the expiration of the nine months, the mixture had a nauseating odour and an alkaline reaction. The flesh had a reddish colour and the filtered liquid gave characteristic reactions for albumins. It was possible to isolate the oxalic acid which, for the most part, remained unaltered. The acid appears to hinder the putrefaction to a certain extent, as evidenced by the relatively good preservation of flesh and albumin. The author considers this fact of importance in the detection of oxalic acid in toxicological cases.—J. L. B.

XIX.—PAPER, PASTEBOARD, Etc.

Papers, Tub-sized, Cost of Drying. C. Beadle. The Paper-maker and Brit. Paper Trade J. 1896, 11, 9–13 and 77–79.

IN drying paper after tub-sizing, the wet paper is generally caused to pass over skeleton drums, in which fans are made to revolve. The air is heated by means of steam pipes which are placed in stages, and so gradually raise the temperature of the air from the floor to the roof and thus maintain its capacity for moisture. This method the author calls the indirect method.

In the direct method, the air is drawn into the building by a fan through a series of cast-iron pipes placed over a coke-furnace. The defect in this method is that the pipes get unevenly heated, those at the bottom becoming red-hot, but this could be easily prevented by using different thicknesses of a non-conducting material, such as asbestos.

Another method of drying coming into use is the method of festooning, in which the paper is carried over laths by a travelling band, in loops about 5 ft. long. This method is specially adapted for surface-coated paper, as the coated surface is dried without being touched.

In the comparison of cost the skeleton drums were used. Data are given, and therefrom the author maintains that the cost of circulating the air bears no fixed relation to that of heating it, and that no conclusions can be come to in regard to cost per hour. When, however, the cost per ton of paper is taken, it is found that there is a direct relationship between this and the humidity of the outside atmosphere.

The direct system is found to be the most economical, as the air is heated directly, and no waste of heat occurs by radiation, &c., as in the indirect method. The mean cost per ton in the indirect method, was found to be 11s. 8d., and in the direct method 10s. 5d., thus being a saving of 1s. 3d. per ton. Coke was used in the furnace for heating the tubes, and an experiment proved that this was 1.8 times as expensive as coal, so that supposing coal to have been used in the direct method instead of coke, with the same efficiency of furnace, the saving in cost would have been 3s. 4d. per ton of paper, or 28 per cent. over the cost of drying by the indirect method of heating.

—S. P. E.

Modern Paper, Durability of. W. Herzberg. Die Chem. Ind. 1895, 18, 476–479.

BECAUSE paper made in former ages from rags only, has proved highly durable and been found in good condition even centuries after manufacture, it is frequently assumed that production from pure rag-pulp is still at the present day an essential and sufficient condition to ensure an equal degree of permanence. This conclusion the author considers to be too far reaching, since the manufacturing process now used differs widely from that formerly in vogue. The preliminary treatment of the rags by boiling with lime, soda, &c. is probably an improvement—resulting in less injury to the fibre—on the old putrefaction process. The modern bleaching process with chloride of lime is, however, a more serious factor. Undoubtedly, at this stage the fibre is more or less attacked, although there is no reason to suppose that its resisting power is seriously impaired. The danger lies rather in the incomplete removal, from the pulp, of decomposition products—especially calcium chloride. The latter in contact with alum (added during sizing) would give rise to aluminium chloride—a substance which readily gives off free hydrochloric acid, and, therefore, must exert a destructive action on cellulose. Again, when "antichlor" (sodium thiosulphate, &c.) is used to destroy excess of bleach, free sulphur is always deposited on the fibre, and this will in the course of time exert an injurious effect. Another possible source of weakness is the substitution of rosin for animal sizing. Mineral loading and staining materials may in general be regarded as inert bodies, having no action on cellulose. Some varieties of ultramarine, however, are apt to liberate free sulphur after a time.

As regards the durability of papers produced, wholly or partially, from wood-cellulose, esparto, &c., opinions are

still divided, some holding that these rag substitutes should never be used for paper that is intended to remain sound for long periods, and *vice versa*. In the case of unbleached cellulose and ground wood no doubt exists; these materials are known to deteriorate rapidly.

The author concludes, therefore, that this question of durability can only be definitely decided by series of systematic experiments extending over a long period of time.—H. T. P.

Blotting Paper, Absorptive Power of. G. Lanbeck. Mitt. Techn. Gewerbe-Museums, 1895, 11—12, 301—303.

THE author has made experiments with a specially prepared blotting paper containing 0.8 per cent. of ash, and with the same blotting paper loaded with various proportions of mineral matter, his object being to determine whether the presence of ash influenced adversely the absorptive power of the paper. The loading material used was "asbestos" and it was found that as much as 11 per cent. might be present without diminishing the capillarity of the paper which, however, fell off when the percentage of ash was further increased. The author points out that the presence of loading material may not be disadvantageous in cases where the spaces between adjacent fibres of the paper are larger than is necessary, but that when the quantity of loading is excessive the spaces on which absorption depends may become unduly congested.—B. B.

Plant Tissues, The origin of the Unsaturated Constituents of. C. F. Cross, E. J. Bevan and C. Smith. Ber. 1895, 1940.

See under XXIV., page 300.

PATENTS.

Vegetable Parchment Paper, Improvements connected with the Manufacture of. H. Sweetapple, Liverpool. Eng. Pat. 24,826, Dec. 21, 1891.

THE object of this invention is to produce vegetable parchment paper from raw paper web, by machinery consisting of a series of tanks containing the various liquids, with propelling winches or rollers at different points along its length and washing devices between the different stages of the process, the paper being introduced at one end as raw paper, passed in a continuous web and delivered as complete parchmentised paper at the other end. The machine includes an acid-treating apparatus, a bath containing water through which the acid-treated paper is passed, and by which the recovery of the acid is effected, a separate washing apparatus, and suitable nipping and propelling rollers, and vertical jet washing devices.—C. F. C.

Paper Making, Improvements in or connected with Machines for Grinding Pulp, Dyes, and the like for. G. Hibbert, Gateshead-on-Tyne. Eng. Pat. 25,040, Dec. 21, 1894.

THIS invention relates to improvements in a combined pulp refining engine and water mixer, and lifter used in pulp and paper making, and also for mixing and grinding colours, dyes, and other materials for paper and pulp making. Inventor claims in such engine the employment of a casing containing two revolving discs mounted on shafts and working in opposite directions, by which means the material being operated upon, is kept longer in the faces; the use of a centrifugal pump on the back of one of the discs for the purpose of lifting the backwater and better mixing the stuffs being operated upon; and the use of a hollow shaft by which the material is conveyed direct to the faces and so insures the stuff being operated upon before being discharged.—C. F. C.

Dandy Rolls for Paper Making, An Improvement in. John Lister, Leslie, North Britain. Eng. Pat. 797, Jan. 12, 1895.

THE spindle of the dandy roll is made hollow and perforated and is connected with a supply of steam. When the dandy roll is working, a number of fine jets of steam, issuing from the perforations, impinge upon the inner surface of the dandy roll cover, this process preventing the accumulation of froth upon the exterior.—S. P. E.

Paper, Improvements in Strainer Plates used in the Manufacture of. H. B. Watson and J. S. Watson, Newcastle-on-Tyne. Eng. Pat. 22,551, Nov. 27, 1895.

STRAINER plates, especially in oscillating paper pulp strainers, are at present arranged so that the paper stuff is preferably caused to travel in a direction at right angles to the slits, and as it is imperative in suction strainers to have strengthening ribs on the underside of such strainer plates, a certain amount of clean stuff is wasted by its rapid flow across these non-slitted strengthening bars.

According to the present invention, strainer plates are so constructed that the strengthening bars do not run across the plates, but end at a mid tie-bar, from which, to the opposite side, similar strengthening bars secure the necessary rigidity of the complete plate. By this contrivance the stuff is no longer able to avoid passing over the straining slits, as it does at present when the strengthening bars extend uninterruptedly across the plate, and a maximum amount of slit area is secured.—C. F. C.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Hydrobromic and Hydriodic Acids, Preparation of. J. H. Kastle and J. H. Bullock. Amer. Chem. J. 18, 105—111.

FOR the preparation of the first-named acid the method here proposed is considered simpler and better than either Erdmann's or Champion and Pellet's process. It is based on the reaction between bromine and naphthalene, which results in the evolution of hydrobromic acid gas. The naphthalene is dissolved in orthoxylenes, or petroleum distilling above 150° C., and the bromine is run slowly in under the surface. The effluent gas is allowed to pass through a concentrated solution of the same acid, containing in suspension amorphous phosphorus, and also through a tube containing a further supply of this latter substance. The acid and phosphorus remove any traces of free bromine and leave the gas, after drying, perfectly pure and colourless.

The operation is as easy and rapid as the preparation of hydrochloric acid from sodium chloride and sulphuric acid, and can be rendered automatic by controlling the flow of bromine into the naphthalene. When pure naphthalene is not available, "moth balls," consisting chiefly of this body, will do equally well.

From five series of quantitative experiments, the amount of hydrobromic acid produced came to an average of within about 9 per cent. of the theoretical yield of the bromine consumed. The method is recommended for lecture work and for preparing the acid in quantity.

The method adopted for preparing hydriodic acid is based on the reaction between iodine and colophony when heated together. It was first proposed by Etard and Moissan (Bull. Soc. Chim. 34, 69), but in the original form the acid is impure, and the following improvement has been devised:—

Equal weights of iodine and fine resin, both in an intimate state of division, are mixed with a slight excess of white sand, and gently heated in a retort. The iodine and brown liquor distilling over along with the acid are condensed in a Woulff's bottle, or in the attached U-tube containing red phosphorus, and, after passing through drying tubes, the pure hydriodic acid can be collected by displacement of air. The yield amounts to 5.4 parts of acid per 10 parts of iodine employed.

There is an entire freedom from danger of explosion by these methods, and no risk of the apparatus becoming choked by bromide or iodide of phosphorus as in other processes where this latter body is employed.—C. S.

Airol, A new Substitute for Iodoform. Therapeut. Monatsh. 1896, 10, 86.

THIS preparation, which was first described by Lüdy, is a basic bismuth-oxyiodide gallate. It is closely related to "Dermatol," a basic bismuth-gallate.

Airol is a greyish-green powder, stable towards light, possessing neither smell nor taste, and readily soluble in

sodium hydroxide and dilute mineral acids. It becomes gradually red in moist air, with the formation of a more basic compound containing less iodine.

Haegler has obtained satisfactory clinical results with airoil, it is less poisonous than iodoform, and not more poisonous than dermatol.—J. L. B.

Eugenol, Some Derivatives of [Vanillin]. Ch. Gassmann and E. Krafft. Bull. Soc. Ind. Mulhouse, 1895, 263—267.

WHEN eugenol (*p*-hydroxy-*m*-methoxy-allyl-benzene) is cohobated with chloroacetic acid in presence of caustic soda for 20 hours, and the melt is subsequently acidulated with hydrochloric acid, eugenol-acetic acid—

separates out and, after crystallisation from water or 50 per cent. alcohol, forms white needles melting at 75° C., easily soluble in hot water, alcohol, and acetone, and volatile with superheated steam. By heating this acid for 24 hours at 150° C. with potash and amyl alcohol it is converted into iso-eugenol acetic acid—

which crystallises from alcohol, melting at 92—94° C. The same product can also be obtained by the action of chloroacetic acid and caustic potash on iso-eugenol, or by heating eugenol acetic acid with caustic soda for a short time at 200° C. When the sodium salt of this acid is oxidised with potassium permanganate and acetic acid, it yields acetaldehyde and vanillin-acetic acid—

which melts at 187° C. (Elkon, Ber., 19, 3055.) This latter product, when heated with twice its weight of phosphorus pentachloride at 130° C. until dissolved, and then poured into hot water, gives vanillin on evaporation or extraction, which was identified by its smell and melting point, 80° C.—T. A. L.

Rhodinol or Geraniol. H. Erdmann and P. Huth.

J. Prakt. Chem. 53, 1896, 42—46.

ACCORDING to the authors, the new terpene alcohol, $C_{10}H_{18}O$, which Hesse obtained by purifying geranium oil from the island Réunion, and termed "Réuniol," is identical with rhodinol, the principal fluid constituent of otto of roses. Rhodinol is further characterised by its diphenylmethane derivative $(C_6H_5)_2C:N(CO.OCC_{10}H_{17})$, which melts at 84° C., and crystallises from 80 per cent. spirit in long silky unacted needles. It is proposed that the term rhodinol shall be reserved as a scientific name for the chief fluid constituent of otto of roses. In commerce, however, it is necessary to employ both the terms geraniol and rhodinol since they designate oils of different origin, which, although undistinguishable by analysis, exhibit slight differences in taste and smell in the same way that alcohol differs when obtained from wine, corn, potatoes, or roots.—T. A. L.

Geraniol and Rhodinol. J. Bertram and E. Gildemeister.

J. Prakt. Chem. 53, 1896, 225.

THE authors review the literature concerning these substances and summarise it as follows:—

(1.) The alcoholic constituents, boiling about 230°, of the essential oils of the geranium, citronella, and rose, consist entirely or nearly entirely of geraniol, as also does the liearhodol, described by Barbier.

(2.) The fractions of the different pelargonium and geranium oils boiling at 225°—230°, contain another alcohol in addition to geraniol.

They find that the preparations from different sources, designated rhodinol, are not pure substances. These agree in containing geraniol, but in very varying quantity.

—A. C. W.

Réuniol, Rhodinol, and Geraniol, the alleged Identity of. A. Hesse. J. Prakt. Chem. 53, 1896, 238.

THE réuniol discovered by the author in pelargonium oils has been found in Wallach's laboratory to be a terpene alcohol of the formula $C_{10}H_{18}O$. It differs from geraniol, $C_{10}H_{18}O$,

in constitution and properties. Rhodinol is an impure réuniol. Prepared according to Ger. Pat. 80,007 of the firm of Gilliard, P. Monnet, and Cartier, from French pelargonium oil, rhodinol, in consequence of the large proportion of geraniol it contains, differs completely from réuniol.

—A. C. W.

PATENTS.

Vanillin, Improvements in the Manufacture of. M. O. and A. Verley, Paris. Eng. Pat. 24,446, Dec. 15, 1894.

THE process consists in electrolytically oxidising a solution of iso-eugenate of soda (or other convenient base) treating the resulting product with an acid and separating the vanillin so produced.—C. F. C.

Ethers of Para-lactylamidophenol, Manufacture of. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Höchst a/M., Germany. Eng. Pat. 2427, Feb. 4, 1895.

To prepare lactyl-*p*-phenetidine, equal molecular proportions of *p*-amidophenol and lactic acid are heated to 170°—180° until the formation of water ceases. The melt is then dissolved in water, and after the addition of animal charcoal is crystallised from the aqueous solution. The *p*-lactylamidophenol thus obtained is dissolved in dilute alcohol, and heated with the calculated quantity of alkali and ethyl bromide, chloride, or iodide, or salts of ethyl sulphuric acid, in a closed vessel on a water-bath for 4—5 hours. The alcohol is then distilled off, and the residue is crystallised from hot water.

By substituting methyl halogen derivatives or salts of methyl sulphuric acid for the ethyl compounds, *p*-lactyl anisidine is obtained.—C. F. C.

Benzamide-o-Sulphonic Acid and of Saccharin and other Derivatives thereof, The Manufacture of. H. E. Newton, London. From "The Farbenfabriken vorm. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 3930, 1895.

THE basis of this patent is the preparation of benzamide-*o*-sulphonic acid by heating benzene-*o*-sulpho-carboxylic acid, or salts of the acid with ammonium sulpho-cyanate.

From the product they proceed to "Saccharin" by the following stages: (1.) Treatment of the salts of the acid with $POCl_3$, PCl_5 , &c. (2.) Treatment of the resulting chloride with ammonia to produce the corresponding amide. (3.) Hydrolysing the benzamide group by heating with sodium hydroxide solution containing 4 per cent. of NaOH. (4.) Finally precipitating the saccharin by acidulating the solution from (3).

The specification contains a full statement of the advantages of the process over that in which benzene-ortho-sulphonic carboxylic acid is used initially.—C. F. C.

Assimilable Iron Compounds, Manufacture of. O. Imray, London. From "The Farbwerke vorm. Meister, Lucius, and Brüning," Höchst a/M., Germany. Eng. Pat. 7169, April 8, 1895.

WHEN, previously freed from albumin and milk-sugar, is treated with barium or calcium salts to throw down the phosphates, and after the excess of the reagent is removed, an iron compound is precipitated by the addition of ferric chloride in the hot. It forms a heavy brown powder, containing about 30 per cent. of iron, soluble in alkalis and alkaline carbonates; and it is only decomposed by sulphides and ferrocyanides after standing some time. It is adapted for use in medicine.—F. H. L.

Chemical Compounds containing Sulphur from Derivatives of Cinnamic Acid, The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vorm. F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 8425, April 29, 1895.

Two parts of the ethylic salt of cinnamic acid and 1 part of sulphur are heated for 8 to 10 hours at 250° — 260° C. After the alcohol has distilled off, the mass is cooled, dissolved in hot spirit, decolorised with animal charcoal, and crystallised several times. The product has the formula $C_{11}H_8S_2O$. It forms yellowish, odourless plates, soluble in benzene, ether, acetone, fats, &c.; but it is almost insoluble in water. On boiling with caustic soda, it is decomposed, acetophenone being produced. Other alkyl salts of cinnamic acid may be employed in an analogous manner. The new thio-compound is claimed as suitable for therapeutical purposes.—F. H. L.

Vanillin, Improvements in the Manufacture or Production of. W. Majert, Falkenberg, Prussia. Eng. Pat. 21, Jan. 1, 1896.

16.4 KILOS. of iso-eugenol, 4.0 of caustic soda, and 25.6 of the sodium salt of chloronitrobenzene sulphonic acid, or 30.0 of the corresponding bromo-compound, are dissolved in water and boiled under an inverted condenser for 12 hours. The resulting sodium salt is salted out, and forms a brownish gum-like product. 37.6 kilos. are then oxidised with 32 kilos. of sodium bichromate and 445 of 10 per cent. sulphuric acid. After boiling for 6 hours, the liquid is made alkaline, the chromium hydrate filtered off, 10 kilos. of caustic soda added, the whole again boiled till the yellow colour no longer increases in intensity, then acidified with dilute sulphuric acid, and the vanillin extracted with ether. The extract is shaken with an aqueous solution of sodium bisulphite, and the resulting compound decomposed with the necessary amount of acid; the vanillin being finally re-crystallised from benzene.

—F. H. L.

XXI.—PHOTOGRAPHY.

Ferrous Oxalate Development, Use of Clearing-Bath after. C. H. Bothamley. Photography, 1896, 8, 98.

DURING ferrous oxalate development, a part of that salt becomes peroxidised, and in the absence of free acid, is converted into a basic ferric oxalate; it is probable that the deposition of this salt in the film on subsequent washing produces the red-brown deposit, which would be most noticeable when the wash-water is very hard. The presence of free acid in sufficient quantity prevents the precipitation of this substance by the formation of a soluble ferric salt; and the good effect of adding a little sulphuric acid to the developer is thus explained. To prevent the formation of the coloured deposit, the plate is dipped before washing into a 3 to 4 per cent. alum solution containing a little oxalic acid. This acid has the desired effect without seriously injuring the gelatin film.—W. G. M.

PATENT.

Colour Photographs, Improvements in, and Apparatus for Producing and Viewing the same. B. J. Edwards, Hackney. Eng. Pat. 3613, Feb. 19, 1895.

THIS patent contains a description of (1) a device for the production of three coloured negatives on different plates by simultaneous exposure in one camera, and (2) arrangements for viewing the dia-positives prepared from these negatives. An ordinary camera is fitted with two semi-transparent mirrors, consisting of lightly silvered glass plates, set at an angle of 45° to the path of the rays. The front mirror is so arranged that half of the light admitted by the lens is reflected, made to pass through a red screen, and allowed to act on a red-sensitive plate. The second one reflects part of the light transmitted by the former, whence it passes through a yellow or green screen, and acts on the plate for the green sensation. The residual light is used to produce the negative for the blues, the plate being placed in

the usual position, and either sensitised specially for blue, or exposed behind a blue or violet screen. By adjusting the relative amounts of light reflected and transmitted by the mirrors, and also the depth of tint of the screens, the three plates may be arranged to require the same length of exposure. The camera may be made to give stereoscopic pictures if desired; and it will be noticed that two of the negatives are "reversed," the third being in the natural position.

To view the positives, each may be mounted in contact with a transparent medium of the required colour; the three being superimposed by optical means. They may be "projected" by a triple lantern, or by a lantern having only one lens and arranged exactly as the original camera. A composite slide is, however, preferable, and is prepared by making "lantern-slides" on glass from two of the negatives, and on celluloid from the third, in the respective complementary colours, mounting the former film to film with the celluloid in the middle, and throwing a beam of white light through the whole.—F. H. L.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Extraction Apparatus, A New. J. J. L. Van Rijn. Ber. 28, 2387.

THE apparatus consists of a wide glass tube A, drawn out at the end B.

A second tube c, narrowed at three places a, b, c, and having four equally large holes at e.

At the narrow part a is a mark indicating 20 c.c. from the bottom of the tube.

The tube c rests in A by means of pieces of glass rod fused to it at e and f. A funnel tube is suspended, reaching almost to the bottom of C.

The liquid to be extracted (solution of extract, milk, &c.) is introduced through the funnel, by means of a pipette into *x* up to the mark *a*. The ether vapours rising from *K* enter the tube *A* through *B*, warm the inner tube *x*, and rise by *c* into the condenser *D*. The ether then drops through the funnel into the liquid in *x*, becomes saturated with alkaloid or fat and then rises, passing through the holes at *c*. The extraction takes place at a temperature very near the boiling point of the extracting liquid (ether, benzene, &c.) The apparatus is easily cleaned, and is so arranged that for extracting liquids no weighing is required, but the liquid is simply measured.

The special advantage of the apparatus is seen when several estimations of the same liquid or extract are required. A solution of known concentration is made and 20 c.c. introduced into *x*, viz., up to the mark *a*, and the extraction proceeded with in the usual way.—H. M.

Gas Burettes, Modifications of the Hempel and Bunte.
O. Bleier. Ber. 28, 2423.

Fig. 1 is a modification of Hempel's gas burette, and consists of a measuring tube *A*, with which a levelling vessel *B* is connected. At the top of the measuring tube is a capillary *a* fitted with tubing and a clip. At the bottom is a

Fig. 1.

Fig. 2.

three-way tap *h*, which makes the connection either with the outlet *c* or with the levelling vessel.

The gas is drawn through the tube *a*; easily soluble gases are allowed to pass through for a few seconds after the tube is emptied, so that the water adhering to the sides becomes saturated.

Fig. 2 is a modification of Bunte's burette, and may be made from the same by simply shortening the lower end. At the top is a two-way tap, and at the bottom an ordinary glass tap with water outlet drawn to a fine capillary, so that the tube requires 2–3 minutes to empty. From one tap to the other is a space of 100.7–101 c.c. So much water is contained in the cup that when the burette is filled with gas at ordinary atmospheric pressure, water admitted through the two-way tap reaches up to the 0 c.c. mark, thus causing the burette to hold exactly 100 c.c. of gas. All measurements are then taken with the water in the cup at the same level *h*.

The measuring tube is filled with water, and gas allowed to pass through for a few seconds. The absorbing liquid is introduced from the cup, and after shaking and washing with water, the reading is taken. The second absorption

liquid is introduced either by running in at the same time as the first liquid runs out, or by drawing out the first liquid by means of suction, and causing a partial vacuum.—H. M.

Laboratory Apparatus, New. O. Eberhard. Chem. Zeit. 1896, 20, 39.

Receiver for the Fractional Distillation of Fuming Solutions.—The end of the condenser tube *a* is connected by india-rubber tubing with the neck of the receiver *c*; the

receiver has a side tube *g*, which may be joined to a calcium chloride tube. The other end of the receiver is closed by a stop-cock *d*, and the side tube *g* is connected with the receiver-tube beyond *d*, by glass tubing joined with a rubber tube *f*, that may be closed by a pinch-cock or with a glass stop-cock sealed on to the glass tubes themselves. The cocks are only closed when the flask *c* is changed. In this way fume or poisonous gases are prevented from escaping, and the collecting flask may be changed without stopping the distillation. For distillation *in vacuo* either a flask with a side-tube is substituted for *c*, or an ordinary flask is attached by means of a two-holed cork.

Condenser for Use in Distilling Small Quantities of Substances.—A weighed test-tube is inserted in the mouth of the condenser with the aid of an india-rubber joint, and

the tube of the fractionating flask is brought directly into it. The condensation even of volatile substances is satisfactory.—W. G. M.

Pressure Tube for Laboratory Purposes. J. Walter.
J. Prakt. Chem. 1896, 53, [2, 3], 132–139.

The author's pressure tube is designed to prevent the bursting of ordinary sealed glass tubes during heating by subjecting them to increased pressure from without. For this purpose the sealed glass tube is introduced through the bronze cover of the apparatus at *E* into the Mannesmann metal tube *A* which is about 560 mm. long and 32 mm. wide. *B* is hard-soldered to a copper tube of 2 mm. bore connected with a cylinder containing compressed carbon dioxide which is admitted to the tube *A* by opening the

valve *c*. *G* communicates with a gauge for indicating the pressure. The apparatus, mounted for an experiment, is shown in the second figure. When the cover is made of

bronze a washer of lead, &c. is, as a rule, unnecessary, and as soon as the apparatus has been proved to be gas-tight the heating may be begun.

With the above apparatus much thinner sealed tubes may be heated with safety, and in many cases, *e.g.*, in splitting off the SO_3H group by means of dilute sulphuric acid, it is not even necessary to seal up the tubes at all if the apparatus is placed in a vertical position in a suitable heating bath. The action of corrosive vapours on the apparatus may often be prevented by pouring a little paraffin or mineral oil on the surface of the liquid and by employing sufficient pressure, or when heating up to about 140° by corking up the tube. When alkaline liquids are being heated the glass tube may be omitted. The apparatus may also be used for drying or heating *in vacuo*, for distillation under pressure, for the determination of the solubility of gases and of solid substances in liquids at high temperature and pressure, and for the determination of the vapour pressure of liquids at high temperatures.—J. S.

PATENT.

Thermometers, Improvements in. E. M. V. Gibb, London, and G. W. Simpson, London. Eng. Pat. 5653, April 1, 1895.

INSTEAD of the wide enamel backing as usually arranged for chemical, clinical, and other thermometers, a narrow vertical strip only of enamel or other suitable material is used, which is placed immediately behind the liquid column, leaving a clear strip on each side, whereby the graduations, which are marked on the back, are easily seen through these clear portions.—R. S.

INORGANIC CHEMISTRY.— QUANTITATIVE.

Methane and Hydrogen, Determination of, by Explosion. A. H. Gill and S. P. Hunt. J. Amer. Chem. Soc. 1895, 17, 986—994.

The results of the authors' investigations may be summarised as follows:—

1. That the usual method of preparing methane by heating sodium acetate with sodium hydroxide and quick-

lime yields a gas largely contaminated with hydrogen. 2. That the determination of methane and hydrogen by one explosion with oxygen yields results within 0.5 per cent. of the methane and 0.3 per cent. of the hydrogen, whilst with two explosions the limits were 0.2 and 0.3 per cent. respectively for the two gases. 3. When a mixture of hydrogen and methane is exploded with a quantity of oxygen insufficient for both, but more than sufficient for either taken separately, about 60 per cent. of hydrogen, 25 per cent. of methane, and 50 per cent. of oxygen are consumed. 4. The method of determining methane and hydrogen by one explosion with air does not afford accurate results.—J. L. B.

Vitriol, Determination of Arsenic in Concentrated.

G. Hattenauer. Zeits. angew. Chem. 1896, 130—131.

THE smallness of the amount of arsenic necessitates the employment of large quantities of vitriol. The literature of the subject is almost exclusively confined to the reactions of hydrogen sulphide and arsenious and arsenic acids or their salts. Authors note the conditions favourable to a rapid and complete precipitation of arsenic by hydrogen sulphide, but solutions of suitable acidity are supposed to be under examination. Even the instructions given in technical hand-books have been found faulty, since the dilution with water precipitates the lead incompletely as PbSO_4 , and what is precipitated is most difficult to filter off. A further disadvantage is that the after treatment with hydrogen sulphide may precipitate other bases than arsenic, and the arsenic precipitate is usually a mixture of arsenic tri- and pentasulphides with free sulphur.

All these difficulties may be avoided if use be made of the property of arsenic, of being quickly and completely precipitated from solutions containing large excess of hydrochloric acid and if at the same time attention be given to the strength of the acid solution used for precipitation.

The author used for his experiments an acid of sp. gr. 1.815 at 22.5°C . 500 c.c. of this acid were cooled and diluted with 500 c.c. of water. An acid of sp. gr. 1.46 at 15° was produced. 500 c.c. of dilute hydrochloric acid (1:2) were then added to 500 c.c. of the diluted vitriol, the cooling being continued. The author finds that a greater excess of hydrochloric acid than the above has no detrimental effect upon the after precipitation of the arsenic; still the above amount is sufficient to prevent either lead sulphate or lead sulphide from being precipitated, this prevention being the object of its addition. The liquid, which must be cooled as far as possible and kept at a low temperature, is now subjected to a rapid stream of hydrogen sulphide, continuing it at least for 45 minutes. It is better to allow an extra 15 minutes, and then the arsenic pentasulphide, which should be of brilliant yellow colour and curdy, may be immediately filtered off. The degree of dilution obtained by following the directions given above is one which leaves the filter paper unattacked by the acids. No lead was found in the washed precipitate, although the vitriol contained 10 times as much lead as arsenic. The precipitate consists, according to Branner and Tomieck (Monatsh. f. Chem. 8, 607) and Neher (Zeits. anal. Chem. 32, 45, this Journal, 1894, 376) of pure arsenic pentasulphide. The further treatment of this precipitate is carried out in the usual way, according as one desires to weigh it as the sulphide, the oxide, or as magnesium arsenate.

The author concludes by stating that, using his method, the determination of arsenic in concentrated vitriol can be completed in 3—4 hours, and that it is therefore one of the most rapid gravimetric determinations known.—J. B. C. K.

Persulphates, Analysis of. F. Ulzer. Mitt. techn. Gewerbe-Museums in Wien, 1895, [11—12], 310—311.

THE author takes exception to such existing methods for the determination of the available oxygen in persulphates as depend upon the liberation of iodine from potassium iodide in presence of hydrochloric acid, and on the liberation of chlorine by distillation with hydrochloric acid, and determination of the iodine ultimately liberated according to the method of Bunsen. He also considers the process of heating the persulphate with excess of standard oxalic acid in the

presence of dilute sulphuric acid, and titrating the residual oxalic acid by means of potassium permanganate as invalid.

The method adopted by him is as follows:—0.3 gram. of the persulphate is heated with a solution of ammonium ferrous sulphate, containing 1 to 1.5 gram. of the salt and dilute sulphuric acid, either in a stream of carbon dioxide or in an apparatus provided with a Hansen valve. At the end of half an hour oxidation is complete, and the excess of the ferrous salt can be titrated back with potassium permanganate. The results quoted for this method worked on commercial ammonium persulphate, are good. A complete analysis of the salt, which commonly contains ammonium sulphate and bisulphate, may be made by determining the total sulphuric acid (including that resulting from the decomposition of ammonium persulphate, by boiling with hydrochloric acid for some time), estimating the ammonia in the usual way and ascertaining the content of free sulphuric acid by titration, using methyl orange as an indicator. Water must be taken by difference. A sample thus analysed had the following composition:—Ammonium persulphate, 45.61 per cent.; ammonium hydrogen sulphate, 48.77 per cent.; fixed salts, 0.61 per cent.; water, 5.01 per cent. It may be remarked that an aqueous solution of ammonium persulphate of a strength of about 15 grms. of the crude salt per litre, keeps its strength very well.—B. B.

Manganese, Determination of, in Crude Iron. F. Ulzer and J. Buill. Mitt. techn. Gewerbe Museums in Wien, 1895, [11—12], 312, 315.

THE author criticises existing methods for the determination of manganese in crude iron and proposes the following process:—A solution from which the iron has been removed by the use of zinc oxide and containing about 0.1 gram. of manganese, is treated with 20 c.c. of a 0.5 per cent. solution of hydrogen peroxide; caustic soda is added so long as a precipitate appears and the solution is boiled, allowed to cool, treated with a known amount of standard oxalic acid, and 10 to 20 c.c. of pure dilute nitric acid (1:10). The whole is gently warmed until the precipitate is dissolved, finally brought nearly to boiling, and the excess of oxalic acid is titrated back with permanganate. In calculating the content of manganese the composition of the precipitated peroxide is taken as 5 MnO , MnO . The authors state that under the conditions named the excess of hydrogen peroxide used in precipitating the manganese is wholly dissipated. The results of this process as compared with a gravimetric analysis are satisfactory. A rapid method somewhat less exact, but suitable for works tests on ferro-manganese, can be adopted by omitting to remove the iron by means of zinc oxide, and thus carrying out the final titration in a solution coloured by a ferric salt. Dilute sulphuric acid if substituted for dilute nitric acid at the stage of the process in which the manganese peroxide is caused to act upon oxalic acid, leads to low results. The iron under analysis may be conveniently dissolved in a mixture of 10 parts of strong nitric acid to 2 of strong sulphuric acid and 2 of water (all by volume). During evaporation about 10 c.c. of strong hydrochloric acid should be added.—B. B.

Gold, Estimation of, in Brilliant Gold and Enamels. M. Schöner. Ann. de Chim. anal. 1896, 1, 47.

BRIGHT-GOLD is a varnish consisting of a sulpho-organic gold compound, contained in a liquid sufficiently viscous to admit of being painted on the polished surface of glass and ceramics. After "kilning" at a temperature not exceeding a low red heat, a glistening coating of metallic gold results. The colour and lustre are dependent upon the amount and quality of the gold contained in the original liquid. The estimation of the gold cannot be effected by removing the organic matter by ignition, owing to the presence of other metals, such as silver, and of readily fusible bismuth salts, the latter serving as an adhesive between the gold and glass. The author weighs out about 10 grms. of the varnish into a fairly large porcelain crucible, and evaporates the volatile constituents at a gentle heat on a sand-bath, avoiding violent ebullition. The residue is then burnt at the lowest possible temperature, so that the porcelain glaze does not fix gold, the mass is then repeatedly extracted with cold or slightly warm aqua regia, consisting of 2 parts of hydrochloric acid

and 1 part of nitric acid (36° B.). The gold is separated from the combined extracts by reduction in the usual manner with ferrous sulphate. If after treatment with aqua regia the interior of the crucible be spotted of a violet or rose colour, such portions of the crucible must be finely powdered and extracted as before, so that all gold adhering to the glaze may be removed.—J. L. B.

Phosphorus in Phosphor-Bronze, New Method of Estimating. F. Oettel. Chem. Zeit. 1896, 20, 19—20.

FROM 3 to 10 grms. of the bronze are digested with nitric acid; the tin oxide is filtered off, well washed, dried, ignited, and fused in a porcelain crucible for a few minutes with three times its weight of potassium cyanide. The melt is boiled with water, and the reduced tin is filtered off. The solution contains the whole of the phosphorus as potassium phosphate, in addition to potassium cyanate and cyanide; it is boiled with an excess of hydrochloric acid until there is no more smell of hydrocyanic acid; traces of lead and tin are precipitated by hydrogen sulphide and filtered off. The filtrate is boiled, the last traces of hydrogen sulphide are oxidised with a few drops of bromine, and the phosphoric acid is precipitated with magnesia mixture. The volume of solution at this time need not exceed 50 c.c. The presence of arsenic does not interfere with the determination in the least, a part of it being lost on the calcination of the filter, a part on fusion with the cyanide, whilst the remainder is reduced with the metallic tin, which is always found to collect more readily into globules in the presence of arsenic than it is otherwise.

—W. G. M.

Oxygen in Commercial Copper, Determination of.

B. Blount. Analyst, 21, 57.

THE author points out that the unreliability of existing methods for the estimation of oxygen in copper is probably due to the fact that all the oxygen does not exist as cuprous oxide (except in refined ingot copper), but as lead oxide, lead arseniate, &c.

The following process, which was found to be very satisfactory, will act equally well for copper-tin alloys, but not for brass, on account of the difficulty of reducing zinc oxide.

The copper is cut into stout strips and weighed out into a porcelain boat, which is placed in a porcelain tube, and the tube heated in a small blast furnace. Pure dry hydrogen is passed through the tube and the water formed, is collected in a weighed sulphuric acid tube.—A. S.

Thomas Slag, Ground, Improved Method for Estimating Soluble Phosphoric Acid in. F. Mach and M. Passon. Zeits. angew. Chem. 1896, 129.

PRECIPITATION with ammonium molybdate is avoided in this method, and considerable time saved.

100 c.c. of the solution of the phosphoric acid prepared according to Wagner's directions, are placed in a $\frac{1}{2}$ -litre flask, having a long narrow neck; 10 c.c. of concentrated sulphuric acid, 15 c.c. of concentrated nitric acid (to promote quiet ebullition), and a drop of mercury of the size used in the method of Kjeldahl for nitrogen determinations are added, and the mixture is then gradually heated to boiling, until colourless. After cooling, 20 c.c. of a 10 per cent. NaCl solution are added to precipitate the mercury, the liquid is rinsed into a 200 c.c. flask, which is filled up, and 100 c.c. of this filtered solution are then treated with 100 c.c. of the usual ammonium citrate solution and 25 c.c. of magnesium mixture. The remainder of the process is carried out in the usual way.

The authors give results of 28 separate determinations by the usual Wagner method and their own, showing that the greatest difference between the actual amounts of magnesium pyrophosphate obtained by the two methods was 0.0022 gm.

They also remark that there is no danger of the presence of silicic acid in the magnesium pyrophosphate obtained when using their method, whilst by the older method with silicious slags this is a possible impurity.—J. B. C. K.

Metals in Liquids, Estimation of Minute Quantities of, [Drinks] Note on. E. R. Budden and H. Hardy, Analyst, **21**, 12.

THE authors found that in the colorimetric estimation of metals, the presence of sugar, essence of lemon, saccharin alone, and a mixture of saccharin and sugar, made no appreciable alteration of tint. In the colorimetric estimation of iron, the tint was found to darken rapidly if the solution were allowed to stand for any length of time. The authors point out the necessity of making colorimetric tests under exactly similar conditions for any purposes of comparison.

From a number of experiments on the electrolytic determination of metals, it was found that in the case of copper, the results obtained were somewhat low, but on the whole fairly satisfactory. With lead, the results were very unsatisfactory, this being also the case when both copper and lead were present.

The authors state that in their opinion, colorimetric methods are best for estimating small quantities of metals.

—A. S.

ORGANIC CHEMISTRY.—QUALITATIVE.

Alcohol, Molybdic Acid as a Reagent for. E. Merck. Chem. Zeit. 1896, **20**, 228.

As little as 0.02 per cent. of ethyl alcohol or 0.2 per cent. of methyl alcohol may be detected in water by means of molybdic acid. The method which gives the best results is to dissolve the molybdic acid in warm strong sulphuric acid, and to pour the alcoholic liquid gently upon the solution in a test tube at a temperature of 60° C. At the point where the liquids meet, a blue ring appears when alcohol is present, which is always more marked as the percentage increases. On mixing, the ring disappears but it recurs on the addition of fresh molybdenum solution. A number of other substances besides alcohol give the same reaction.—W. G. M.

Acetanilide, Phenacetin, Quinine Sulphate, &c., Scheme for Identification of. E. S. Hyde. J. Amer. Chem. Soc. 1895, **17**, 933—935.

By boiling the substance with caustic potash and chloroform (isonitrile reaction), phenacetin gives this reaction, but

SCHEME FOR THE IDENTIFICATION OF ACETANILIDE, PHENACETIN, QUININE SULPHATE, &c.

Pure Substance.	Melting Point.	Solubility in Water.	Solution of Substance in Water.			
			Boiled with Excess of Caustic Potash and Few Drops of Chloroform.	Ferric Chloride.	Dilute Nitric Acid.	Bromine Water.
Acetanilide (phenylacetamide)— $C_6H_5NH.COCH_3$	113°	Soluble in cold; more so in hot.	Odour of isonitrile.	Yellow solution; red on boiling.	Colourless.	White crystals; para-bromo-acetanilide.
Exalgin (methylphenylacetamide)— $C_6H_5N.CH_3(COCH_3)$	101°	Cold: not very soluble. Hot: easily soluble.	No odour of isonitrile. Class of secondary amines.	Yellow solution; cloudy red on boiling.	Colourless.	No precipitate.
Phenacetin (acetyl-para-amido-phenetol)— $C_6H_4.OC_2H_5.NH.COCH_3$	135°	Soluble with difficulty.	Odour of isonitrile.	Yellow solution; blood-red on boiling.	Cloudy yellow solution. Crystals of nitro-compound.	No precipitate.
Phenecoll hydrochloride (glycocoll para-amido-phenetol)— $C_6H_4 \begin{cases} OC_2H_5 \\ NH.COCH_2.NH_2.HCl \end{cases}$	No m.p. HCl comp.	Very soluble.	Odour of isonitrile.	Yellow solution; darkens and orange precipitate on boiling.	Colourless.	No precipitate.
Salol (phenol salicylate)— $C_6H_4.OH(COO.C_6H_5)$	83°	Soluble with difficulty.	No odour of isonitrile. Yellow solution.	Yellow solution; blood red on boiling.	Colourless.	No precipitate cold; white cloudy compound on boiling.
Resorcinol (meta-hydroxybenzene)— $C_6H_4(OH)_2$	118°	Easily soluble.	No odour of isonitrile. Carmine-red solution.	Dark violet; yellowish on adding drop of sulphuric acid.	Yellow solution.	Yellowish precipitate, dissolving immediately.
Quinine sulphate— $C_{20}H_{24}N_2O_5.H_2SO_4$..	Slightly soluble with few drops of sulphuric acid; dissolves with blue fluorescence.	Base precipitates and dissolves on heating.	Yellow solution.	Colourless, with bluish fluorescence.	Dry substance on porcelain with weak bromine water gives green coloration on addition of two or three drops of ammonia water. Thallicum test.
Antipyrin (phenyldimethyl-pyrazolone)— $HOC_5N_2(CH_3)_2C_6H_5$	113°	Soluble.	Nothing.	Blood-red; disappears on adding a drop of sulphuric acid.	Colourless.	Yellowish-white precipitate.

exalgin being a secondary amine, does not. In carrying out the test it is advisable to make the solution strongly alkaline, so as to ensure complete decomposition, and a quick reaction. (See tabulated scheme above.)

ORGANIC CHEMISTRY.—QUANTITATIVE.

Petroleum Industry, Uniform Methods of Testing, Review of Methods Based on the Degree of Refinement by

Means of Caustic Lye. K. Charitschkoff. Chem. Rev. u. d. Fett u. Harz Ind. 1896, [36], 57—58.

APART from the unreliable test with decinormal sodium hydroxide and phenolphthalein, there are two methods current in Baku for determining the degree to which the alkali process of refining has been performed. In the one a strong soda-lye of 30° to 35° B. is shaken up with twice its volume of petroleum, and the formation of flocculent soaps at the plane of contact of the liquids forms a measure of the degree of impurity still remaining. This test, however, does not suffice for purposes of comparison between different oils, and another method has been adopted wherein 6 per cent. by volume (as compared with the amount of petroleum) of a 2° B. soda solution is used, the agitation being effected at 70°. The aqueous solution

is filtered off and made slightly acid with hydrogen chloride, whereupon any petroleum acids present are liberated and give rise to turbidity in proportion to their amount. The test is rapid and affords a good indication of the comparative purity of different oils; it can be worked on the basis of the production of a certain degree of opacity either with a standard amount of alkali, or with a fixed amount of petroleum. In the case of lubricating oils, to which the test is also applicable, and for which a somewhat higher temperature must be maintained, the degree of impurity is indicated by the amount of insoluble soapy layer formed at the zone of contact, the soaps from the acids of the heavier oils being less soluble than those from oils of lower density.—C. S.

Asphaltum, Use of Acetone in the Technical Analysis of. F. F. Peckham. J. Franklin Inst., **141**, [843], 219—223.

In examining the method advocated by Sadtler (this Journal, 1896, 222), wherein acetone is employed as a solvent for bitumen instead of petroleum spirit, the author tested samples of Trinidad pitch, both crude and purified, by the process described by Miss L. A. Linton (this Journal, 1895, 960), and also by the acetone method. He found that whilst petroleum spirit dissolves more of the bitumen than does acetone, the latter extracts a quantity of non-bituminous and mineral matter more than sufficient to compensate for the deficiency. In other instances, such as the case of a very dry Egyptian asphaltum and an Athabasca River maltha, the solvent power of petroleum spirit greatly surpassed that of acetone, and the author therefore considers that the lack of parallelism observed, puts acetone out of the question as a substitute for the spirit. Besides, its property of dissolving non-bituminous matter is calculated to defeat the object in view, and its action more closely resembles that of the alcohols than that of true solvents of bitumen.—C. S.

Crude Cresol, Approximate Valuation of. A. Schneider. Pharm. Centralhalle, **36**, 552.

This process is founded on a comparison of the intensity of the yellow tint assumed respectively by a pure cresol mixture, and by cresols obtained from the substance examined, when treated with nitric acid and ammonia. Crude cresol is dissolved in soda-lye and the solution is diluted with 5 vols. of water, and the hydrocarbons (naphthalene, &c.) are removed by shaking with benzene, the cresols being separated by means of acid, the pyridines being combined at the same time. The cresols thus separated, are collected, dried with calcium chloride, and distilled. Thus, the pure cresol mixture is prepared. But, instead of this, commercial cresol dehydrated with calcium chloride, may be used. 1 gram. of this pure cresol is dissolved in water, and the solution is diluted to 100 c.c.; it serves as the standard of comparison. 1 gram. of the cresol to be examined, is also dissolved to 100 c.c., a small quantity of powdered quicklime being added in order to seize upon any resinous matters which may be separated, and to increase the solubility of the cresols enclosed by the insoluble matters. 1 c.c. of the solution of the crude cresol is then taken (= 0.01 gram. of the substance), 5 c.c. of dilute nitric acid are added, and the mixture is heated on the water-bath for five minutes. The yellow liquid is then poured into a glass cylinder suitable for colorimetric comparisons, the ringings are added, as also 10 c.c. of liquid ammonia, and the cylinder is filled up with water.

10.85 c.c. of the solution of the pure cresol (= 0.0085 gram. of pure cresol) is treated in the same manner, and the colours of the two solutions are compared. Of an official sample, the colour of 0.01 gram. of crude cresol should not be weaker than that of 0.0085 gram. of pure cresol.

The author assumes as the lowest percentage of an official sample 85 per cent. of pure cresol, since cresols can take up as much as 12 per cent. of water, and 3 per cent. of other impurities may be calculated. A high percentage of water is shown by the circumstance that such samples give with benzene a turbid mixture, whilst anhydrous samples form a clear mixture therewith.—A. S.

Aniline in Presence of Small Quantities of Toluidine, and Toluidine in Presence of Small Quantities of Aniline, Estimation of. P. Dobriner and W. Schranz. Zeits. Anal. Chem., **34**, 734—740.

A METHOD proposed by Reinhardt (Chem. Zeit., **17**, 413; this Journal, 1893, 954) for the determination of aniline in toluidine, has been adapted by the authors for the estimation of aniline, *o*- and *p*-toluidine in commercial aniline oil. The method depends upon the fact that nascent bromine converts aniline into a tribromo derivative and the toluidines into dibromo derivatives. The brominating solution being standardised against pure aniline, the toluidine value is obtained by multiplying the aniline value by $\frac{100.5}{93}$. When an oil contains only aniline and the two toluidines, and is free from water, one titration gives the amounts of the two constituents according to the following equation:—

$$x = 2.3777 vt - 1.3777 a,$$

in which *a* = weight of oil, *x* = amount of aniline, *t* = value of the brominating solution calculated on pure aniline, and *v* = No. of c.c. of brominating solution taken. Then *a* - *x* = amount of toluidine contained in the oil. The method gives very accurate results when detecting and estimating small quantities of toluidine in aniline. In the case of toluidine containing small quantities of aniline, the results obtained are somewhat too high, and even a pure toluidine appears to contain aniline. Correct numbers are, however, obtained by titrating the brominating solution against pure toluidine, and calculating the aniline value *t* by multiplying it by $\frac{93}{100.5}$. It is indeed preferable to titrate the brominating solution against pure aniline and pure toluidine, and, designating these values by *t* and *T*, the amount of aniline is given by the equation—

$$\frac{x}{t} + \frac{x-a}{T} = v.$$

The method can also be employed for the valuation of aniline salt (aniline hydrochloride), which, for the purpose of the analysis, must be dried over sulphuric acid. The formula becomes $X = 2.5102 VT - 1.5102 A$,—*A*, *X*, and *V* having corresponding values to those given above. *T* is the value of the brominating solution in pure aniline hydrochloride, and is obtained from the aniline value *t* by multiplying by $\frac{120.5}{93}$.

All the determinations are carried out according to Reinhardt's directions, except that the hydrobromic acid is replaced by potassium bromide and hydrochloric acid. The end of the reaction is detected by spotting on starch-iodide paper, and in the case of aniline is exceedingly sharp. With *p*-toluidine it is advisable to run in the brominating solution slowly at the beginning and towards the end of the reaction. About 150 c.c. of brominating solution (1 litre corresponding to 8 grms. of aniline) are taken for a determination, the readings being observed very carefully at 15° C. The paper contains a number of analyses, both of mixtures of pure aniline and toluidine, and also of commercial samples.—T. A. L.

Moisture in Aniline, Ortho- and Paratoluidine, Estimation of. P. Dobriner and W. Schranz. Zeits. Anal. Chem., **34**, 740—742.

THE determination depends upon an application of Reinhardt's method (see preceding abstract), by observing the number of c.c. of brominating solution absorbed by equal weights of the moist and dried substances. If *a* c.c. be absorbed by the wet, and *b* c.c. by the dry substance, then *F*, the percentage amount of moisture, can be calculated from the proportion:—*a* : *b* = (100 - *F*) : 100. Aniline and *o*-toluidine can be obtained anhydrous by treatment with fused potassium carbonate, whilst for technical purposes it is sufficient to distil *p*-toluidine, and after 10 per cent. have distilled over, to consider the residue as dry. Of several samples of commercial *p*-toluidine examined, none contained more than 1 per cent. of water.—T. A. L.

Cold Saponification. R. Henriques. *Zeits. f. angew. Chem.* 1895, 721.

All glycerides capable of saponification according to the method of the Koettstorfer test, may also be saponified in the cold by means of petroleum spirit and semi-normal or normal alcoholic soda. The process is carried out by dissolving from 4 to 5 grms. of the oil or fat in 25 c.c. of petroleum spirit, and adding to this solution 25 c.c. of normal alcoholic soda. Saponification sets in almost immediately, but it is advisable to allow the mixture to stand overnight, and in the case of the waxes and wool fars with difficulty saponifiable, 24 hours should be allowed. The samples may then be proceeded with in the usual manner by titration. This cold saponification test appears also preferable to the usual form of the Reichert-Meißl test. For this purpose 5 grms. of the oil are dissolved in 25 c.c. of petroleum spirit and saponified in the manner above mentioned. On the following morning the saponified mixture is evaporated to dryness, the dry residue transferred to the distillation flask, the dish washed with the usual quantity of hot water, which is then added to the contents of the distillation flask. Distillation is then carried out in the usual manner.—C. O. W.

Tannin, Determination of, by Metallic Oxides. W. H. Krug. *J. Amer. Chem. Soc.* 1895, 17, 811—814.

The oxides were applied in the manner adopted for hide powder by the "shaker method" (this Journal, 1894, 494). In the case of lead oxide it was found that after 4 grms. of it had been shaken with 75 c.c. of a dilute liquor (containing 2 grms. per 100 c.c. of an extract which yielded 42.35 per cent. of soluble matter) for 4 hours, the tannin had not been completely absorbed, and two days' rest were needed before the tannin had disappeared from the solution. Two grms. of zinc oxide, used under exactly the same conditions, required one week before absorption was complete; a very small quantity of zinc oxide was found in the ash of the non-tannins, and in the case of lead oxide none was dissolved. The use of both oxides is, however, prohibited on account of the slowness of their action.

Magnesia is of no use, because it dissolves to a considerable and variable amount in the liquor, thus increasing the percentage of non-tannin and decreasing that of the tannin.

Yellow mercuric oxide gave good results in a comparatively short time, as is indicated by the following table. The diluted extract was that mentioned above, and contained in 25 c.c. 0.0113 gm. of ash:—

Method.	H ₂ O used.	Diluted Extract used.	Filtrate evaporated.	Weight of Residue.	Tannin in Extract.	Weight of Ash in Residue.
	Grms.	C.c.	C.c.	Grm.	Per Cent.	Grm.
Stood 48 hours, with occasional shaking	4.0	75	25	0.0833	25.60	0.0070
" 48 " " " " " " " " " "	4.0	75	25	0.0820	25.77	0.0077
Shaken 1½ hours; stood overnight	4.0	75	25	0.0842	25.51	..
" 3½ " " " " " " " " " "	4.0	75	25	0.0863	25.60	0.0081
" 4 " " " " " " " " " "	4.0	75	25	0.0839	25.57	0.0084
" 4 " " " " " " " " " "	4.0	75	20	0.0638	26.41	0.0065
" 4 " " " " " " " " " "	4.0	75	20	0.0632	25.65	0.0103
" 4 " " " " " " " " " "	4.0	75	25	0.0863	25.60	0.0083

The author claims that these figures (and some more of the same character not here quoted) show that, even though the conditions may be varied, fairly concordant results may be obtained with mercuric oxide, provided that care be taken to ensure complete absorption of tannin before filtration. The end of the reaction is indicated by the fact that the yellow oxide no longer sinks to the bottom, but the whole mass partly gelatinises and becomes dirty brown. A clear filtrate, free from tannin and mercury, can then be readily obtained. The figures show that a certain amount of the ash present in the extract is held back by the oxide, but the error introduced is quite constant and very small. The time required is somewhat longer than that necessary for the analysis by the hide-powder method.—A. G. B.

Acetone, Determination of, in Wood-Spirit and Crude Acetone. M. Klar. *Die Chem. Ind.* 1896, 19, 73—79.

An investigation as to the relative merits of Krämer's and Messinger's methods.

Krämer's Method.—This has been officially adopted in Germany for the examination of wood-spirit intended for denaturing purposes. The following *modus operandi* is (officially) laid down:—10 c.c. of the sample are diluted to 100 c.c. with water, 1 c.c. of this solution is transferred to a narrow cylinder and thoroughly shaken with 10 c.c. of twice-normal NaHO, then with 5 c.c. of twice-normal iodine. The iodoform produced is dissolved by agitation in 10 c.c. of ether (sp. gr. 0.722), 5 c.c. of the ethereal layer are then withdrawn, allowed to evaporate spontaneously on a watch-glass, dried for two hours over sulphuric acid, and the residue weighed. Its weight should not be less than 0.07 gm. The above amount of iodoform is con-

siderably less than that theoretically obtainable from spirit containing 30 per cent. of acetone (the minimum standard). The method is therefore merely empirical, but, even as such, yields, according to the author, results so irregular as to be quite useless for purposes of comparison. Correct results—corresponding to the amount of acetone really present—may be obtained, however, Krämer's method being in other respects adhered to, by reducing the quantity of acetone operated on. The spirit under examination should be diluted 40 times, and 1 c.c. of this solution used. Secondly, the iodine must be added slowly (in 3—4 minutes), drop by drop, with constant agitation; and the ether used for extraction must be free from alcohol, aldehyde, and peroxides.

Messinger's Method.—In this process the iodoform reaction is applied volumetrically.

One c.c. of the diluted wood-spirit (1:10) contained in a stoppered flask is mixed with 20 c.c. of normal NaHO (accurately measured). About 20 c.c. of $\frac{N}{5}$ iodine is then run in slowly (3—4 minutes), drop by drop, the contents of the flask being vigorously rotated the whole of the time. 20 c.c. of normal H₂SO₄ (accurately measured) is next added, and allowed to act for 1—2 minutes (this is essential to ensure complete decomposition of iodates and iodides), after which the residual iodine is titrated by $\frac{N}{10}$ Na₂S₂O₃ in the usual way. (1 c.c. $\frac{N}{5}$ iodine = 0.001333 acetone.) A determination of acetone by this method can be made in 10 minutes. The results obtained are very concordant on repetition, and correspond accurately with theory. The official adoption of this process in place of Krämer's is therefore strongly recommended.—H. T. P.

Acetone, Determination of. G. Krämer. *Die Chem. Ind.* 1896, 19, 79.

REFERRING to Klar's communication (see preceding abstract) on this subject, the author states that in the official version of his (Krämer's) method, certain precautions (Ber. 1880, 1000) that must be observed in order to obtain exact results are omitted—for the sake of simplicity and because

a moderate degree of accuracy suffices in practice. Apart from this, the author ascribes the grossly inaccurate results obtained by Klar to faulty manipulation, and supports his contention by some comparative determinations made by his and Messinger's methods.—H. T. P.

Alkaloids, Acidimetric Estimation of Vegetable. L. F. Kebler. *J. Franklin Inst.* 1896, **141**, 141—147.

The author finds that methyl orange is unsuitable for titrating alkaloids, especially in dilute solutions. The following indicators, arranged in their order of merit, *viz.*, hæmatoxylin, Brazil wood, and cochineal, gave very promising results. The author also appends a list of the literature of the subject.—J. S.

Nicotine and Ammonia in Tobacco, Estimation of. R. Kissling. *Zeits. Anal. Chem.* **34**, 731—734.

The author criticises a recent publication by Vedrodi (*Zeits. Anal. Chem.* **34**, 413), who, in a paper on the estimation of ammonia together with nicotine in tobacco, described several modifications of the author's original method (*Zeits. Anal. Chem.* **21**, 76; this Journal, 1882, 200) to which he now takes exception. He points out that the numbers obtained by Vedrodi are too low, since the $\frac{N}{3}$ sulphuric acid employed by the latter, containing 32.61 grms. of sulphuric acid in a litre, combines with equimolecular proportions of ammonia and nicotine, *i.e.* 1 c.c. saturates 0.01132 gm. of ammonia (NH_3), or 0.1078 gm. of nicotine ($\text{C}_{10}\text{H}_{14}\text{N}_2$). The following method, according to the author, must be applied in order to determine the various nitrogen compounds in tobacco, more especially nicotine, ammonia, amide compounds, and albumin. After determining in one portion, the nicotine, an extract is made by boiling 10 grms. of another portion of the tobacco in powder with 100 c.c. of 40 per cent. alcohol under an inverted condenser. When cold, the extract is filtered and the alcohol is distilled from an aliquot part. The residue is diluted with water, acidulated with sulphuric acid, and treated with phosphomolybdic acid to remove albuminoids, peptones, nicotine, and ammonia. The aqueous solution, made up to 100 c.c., is filtered, and the nitrogen is determined in 75 c.c. of it, evaporated with barium chloride. A third portion of the tobacco (20 grms.) is warmed with about 350 grms. of very dilute sulphuric acid. The total weight is then made up to 400 grms., of which 200 grms. are filtered off, the solution being treated with mercuric chloride to remove albuminoids and organic matter. An aliquot part having been filtered off, the mercury is removed with sulphuretted hydrogen, and the amides are converted into ammonia and amido acids by boiling for an hour. After making alkaline, the nicotine and ammonia are distilled off with steam into normal sulphuric acid. From the numbers obtained, it is possible to calculate the amount of nicotine, ammonia, and amides contained in the original tobacco, that obtained for the amido nitrogen being halved. Subtracting these numbers from the total nitrogen found, the remainder is calculated as albumin.—T. A. L.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Saturation and Critical Temperatures. Crismer and Motten. *Ass. Bodge des Chim. Chem. Zeit.* 1896, **20**, 41.

By plotting a curve of solubility of any substance in a suitable solvent, using as abscissa the temperatures at which homogeneous solutions become turbid, and as ordinates the weights or volumes of the substances examined per 100 parts of solution, the curve will be separable into three parts:—(1.) The zone of non-saturation, which corresponds to the solutions of 0—30—40 per cent., and which gradually increases as x (the temperature) is raised; (2.) the zone in which x is constant, whilst y (the percentage) varies (40—60 per cent.); this is the zone of the constant magnitude of critical temperatures; and (3.) the zone of over-saturation, in which x is smaller, whilst y becomes greater (60—100 per cent.). In the first of these

three zones the position of x is strongly affected by a very small variation in y ; thus a solution of 8.4 per cent. sulphur in a mixture of 1 vol. of absolute alcohol with 2 vols. of benzene becomes turbid at 90° , and a solution of 9.2 per cent. at 100.5° . Hence it is possible to obtain accurate estimations by observing the saturation temperatures. A known weight of dynamite may be placed in a closed glass tube or flask with a measured volume of absolute alcohol and heated to 45°C . The saturation temperature, determined to one-tenth of a degree, gives y (the percentage of nitroglycerin in solution), and as the volume of alcohol is known, the quantity of the nitroglycerin in the dynamite can be estimated. Ordinary gunpowder may be similarly treated with a mixture of 1 vol. of absolute alcohol and 2 vols. of benzene. A curve expressing the critical points of a substance in more or less diluted samples of alcohol is almost a straight line, y being the temperature and x the percentage of water in the alcohol. A weighed quantity of butter may be treated with a measured volume of absolute alcohol and the critical point taken without filtering, as the presence of casein does not interfere. This critical temperature then shows the extent to which the alcohol has been diluted, and hence the water in the butter taken. In the absence of salt the results are very accurate, but when any appreciable quantity of salt is present there may be an error of from 0.5 to 1 per cent. The authors give the critical temperatures of 23 fats and oils in the original paper.—W. G. M.

Graphite, Occurrence of, in Russia. R. Helmhaecker. *Berg u. Hütt. Zeit.* 1896, **55**, 29.

ALIBER found graphite in 1842 in the Tenkinski Mountains (Irkutsk) in a hill 2,240 m. high, composed on the north of granite and on the south of crystalline limestone and crystalline schists. In 1856 he formed the Maryinski Graphite Mining Co. The graphite contains 83.8 to 85.6 of carbon, with 11.1 to 15.7 of ash, and 3.8 per cent. of water, and picked samples gave better results still. It is won so easily that its price is practically determined by the cost of transport. It is used for pencils and for crucibles. In 1859—1863 Siderow discovered and worked graphite in the most northern division of Turuchansk (Jenisejsk), on the rivers Niznaja-Tunguzka and Kurejka. In the neighbourhood there is an outcrop of coal, probably of the Jurassic period, and some hundred versts away graphite occurs in clay slate. It is probable that the graphite owes its origin to the action of volcanic rocks upon the Jurassic coal. This graphite is comparable with that from Cumberland, and contains 89.2—94.3 per cent. of carbon, 9.7—1.4 of ash, and 1.9—0 water. In spite of its abundance the production of the graphite is very variable. A third source of graphite is the Tarbagatai Mountains, in the eastern portion of the Kirghiz steppes, but it contains 10 per cent. of ash and at present finds no market.—W. G. M.

Acetic Acid and Benzene, Mixtures of, Formation of Layers in. C. E. Lindeberger. *J. Amer. Chem. Soc.* 1895, **17**, 932—933.

ACCORDING to Duclaux (*Ann. Chim. Phys.* 1876, [5], **7**, 267) mixtures of benzene and acetic acid exhibit at certain temperatures the property of layer formation. In the course of an investigation carried out by the author on the vapour tensions of mixtures of benzene and acetic acid, the results were such as to preclude the possibility of this phenomenon. Accordingly, mixtures of pure benzene and pure acetic acid of varying concentrations were exposed to a temperature of -20° , but in no case was a separation into layers observed. It therefore appears that Duclaux's statement with regard to benzene and acetic acid is erroneous, and that the formation of layers is due to the presence of water.—J. L. B.

Plant Tissues, The Origin of the Unsaturated Constituents of. C. F. Cross, E. J. Bevan, and C. Smith. *Ber.* 1895, 1940.

THE formation of fufurals by the action of condensing acids upon the "furfurals" of plant tissues, is accompanied by that of volatile acids. The authors have investigated the

quantitative relationships of these products when formed by the action of boiling aqueous sulphuric acid of varying degrees of condensation. In the case of barley-straw the volatile acid is chiefly acetic acid, and the following yields were obtained:—

Concentration of Acid, Per Cent. H_2SO_4 .	10.	15.	20.	30.	40.	50.
	Per Cent. of Straw.					
Furfural.....	2.0	2.0	4.4	10.1	11.5	11.0
Acetic acid.....	1.7	1.9	3.1	4.3	6.3	14.8

Up to a certain point of concentration of the acid (40 per cent.), the numbers for total yields show progressive increase. Observations upon the relative rate of formation show a more rapid rate of increase of the furfural with increasing concentration of acid. It is concluded that in the earlier stages the furfural and acetic acid originate in a common reaction. This corresponds with what is known of the constitution of the lignocelluloses, which yield furfural on the one hand and acetic acid on the other—products of various processes of condensation and hydrolysis—in quantities proportional to lignification.

The celluloses isolated from the lignocelluloses yield, on boiling with condensing acids, in addition to furfural, chiefly formic acid.

In conclusion the authors discuss the bearing of these observations on the formation in the plant of substances of the R. hexene and benzenoid types of carbon condensation.

—C. F. C.

Autumn Leaves, The Yellow Colouring Matter in.

G. Staats. Ber. 28, 2807.

The yellow autumn leaves of limes digested with boiling alcohol give a deep yellow solution. This yellow colour, however, is not identical with phyloxanthin. By treating the alcoholic solution from autumn leaves of limes and beeches with caustic potash, a reddish-brown precipitate and a yellow solution are formed.

The reddish potassium compound precipitated in this way from limes, dissolves in water with a deep red colour and crystallises from a mixture of alcohol and water in long reddish-yellow needles.

It dissolves in hydrochloric acid, forming again the yellow colour.—H. M.

Diazomethanesulphonic Acid, Preparation from Potassium Cyanide and Sulphurous Acid. H. v. Pechmann and Ph. Manek. Ber. 28, 2374.

By the action of sulphurous acid on potassium cyanide (2 mols. potassium bisulphite to 1 mol. potassium cyanide), the primary and secondary salts of a dibasic acid are formed. The primary salt, $\text{CH}_3\text{NH}_2(\text{SO}_3\text{H})(\text{SO}_3\text{K})$, is with difficulty soluble in water, and the solution is decomposed on boiling.

The secondary salt, $\text{CH}_3\text{NH}_2(\text{SO}_3\text{K})_2$, is very soluble in water and crystallises easily from the same.

The acid is not known in the free state. By action of nitrous acid upon the secondary salt, diazomethane disulphonate of potassium is formed—

which separates out in yellow crystals. This salt dissolves in water, forming a neutral solution, which turns acid on standing, with evolution of nitrogen. In presence of free alkali the solution is fairly stable, and the salt can be crystallised out in this way. It reduces salts of the heavy metals that are reducible, and its solution is slightly decolorised by reducing agents. It is decomposed by acids, losing its nitrogen—

—H. M.

New Books.

WATER-ANALYSIS: A Practical Treatise on the Examination of Potable Water. By J. ALFRED WANKLYN and ERNEST THEOPHROUS CHAPMAN. Tenth Edition. Revised and partly re-written by J. ALFRED WANKLYN, M.R.C.S., formerly Professor of Chemistry in the London Institution, &c. Kegan Paul, Trench, Trübner, and Co., Lim., London. 1896. Price 5s.

A TENTH edition of this work now appears. The author (J. A. Wanklyn) states that he has "For some time paid particular attention to the detail of the estimation of the water-residue, and also to the specific gravity of different waters; and Chapter II. (in the present edition) is re-written." Part of Chapter IV. is re-written, and many additions and emendations are scattered through the work. A new chapter also appears on "Table Waters."

POUVOIR CALORIFIQUE DES COMBUSTIBLES SOLIDES, LIQUIDES, ET GAZEUX. Par M. SCHEURER-KESTNER. G. Masson, 120, Boulevard Saint-Germain, Paris. 1896. Price 5 fr.

SMALL 8vo. volume in paper cover, containing Preface, bibliography of works or articles on Fuels, Thermo-Chemical Problems in connection with Fuels and Calorimetry, and subject-matter covering 270 pages. Finally, a kind of Appendix follows with 13 tables, two of which refer more especially to calculations (a) Of the weight of carbon in the gaseous form, and (b) Of the heat of combustion of gaseous carbon. The work ends with a Table of Contents. The text is illustrated with 44 excellent woodcuts. There are two principal parts into which the work is divided: I., Containing an *exposé* of the methods made use of in calculations of the heat disengaged during combustion; II., Containing the rules to be followed in technical experiments which have for their object the determination of the calorific power of a combustible. These two principal parts are subdivided as follows:—I. Definitions. Methods. Calorimeters. Mineral, Ligneous, and Liquid Combustibles. Pyrogenic Combustibles. Gaseous Combustibles. Special Calorimeters for the Combustion of Gases. Coal-Gas, &c. II. Calorific Power of Coal burnt in Steam-Boiler Furnaces. Calculation of Gaseous Volume in accordance with Analysis. Determination of Gaseous Volume by the Anemometer, by a formula based on the Outflow of Gas, by means of a Calorimetric Calculation. Determination of the Temperatures of Gases at their Point of Issue. Transformation of Observed Data into Calories, &c.

TRAITÉ DES MATIÈRES COLORANTES ORGANIQUES ARTIFICIELLES, DE LEUR PRÉPARATION INDUSTRIELLE, ET LEURS APPLICATIONS. Par LÉON LEFÈVRE, Ingénieur (E.I.R.), Préparateur de Chimie à l'École Polytechnique. Préface de Ed. GRIMAUX, Membre de l'Institut (Académie des Sciences). G. Masson, 120, Boulevard Saint-Germain, Paris. 1896. Price 3l. 12s. H. Gravel and Co., 33, King Street, Covent Garden, London.

THIS complete treatise is contained in two large 8vo. volumes, bound in cloth, and containing 1573 pages of subject-matter, terminating in Index lists of Patents—French and German, with the pages in the work given, in which references to them may be found. An Alphabetical Index of the general subject-matter finally ends the work. The text is illustrated with 31 beautifully executed engravings, representing apparatus and plant used in the manufacture of dyestuffs, and 261 dyed and printed patterns on silk, wool, cotton, paper, and leather, these patterns being specially prepared under the direction of M. Lefèvre. The work is divided into 20 chapters, each of which is subdivided so as to contain: (1.) The Historical Introduction. (2.) Modes of Formation and Constitution. (3.) General Properties and Reactions. (4.) Description of the Individual Colouring Matters in the Groups, with Graphic Formulæ. (5.) Tabular Survey of all the Dyestuffs referred to under (4), (with many others not commercially valuable), giving modes of formation, properties, and commercial names, with also the numbers of the corresponding patent specifications. (6.) Manufacture of the Colours on the Large

Scale, and their Application, illustrated by cuts, diagrams, and dyed and printed patterns. (7.) A List of all the more important Publications; and (8.) The titles and numbers of the Patent Specifications, dealing with the Colouring Matters of the Group. The author pays a special tribute of indebtedness to M. Horace Koechlin, for his aid in the preparation of the printed patterns. The Chapters themselves may be classified as treating of the following subjects: I. Nitro Dyestuffs. II. Azoxy Colours. III. Azo Colours. IV. Hydrazine Colours. V. Indamines. VI. Indones. VII. Oxindamines or Oxazines. VIII. Oxindones. IX. Thiazines. X. Eurbodines. XI. Safranines. XII. Indulines. XIII. Naphthalene Colours. XIV. Colours derived from Quinoline Bases. XV. Diphenylmethane Colours. XVI. Colours derived from Triphenylmethane and its Homologues. Phthalains. XVII. Anthracene Colours. XVIII. Quinone-oxime Colours. XIX. Artificial Indigos. XX. Various Artificial Colours.

HANDBUCH DER CHEMISCHEN TECHNOLOGIE. In Verbindung mit mehreren Gelehrten und Technikern bearbeitet, und herausgegeben von Dr. P. A. BOLLEY und Dr. K. BUNBAUM. Nach dem Tode der Herausgeber fortgesetzt von Dr. C. ENGLER.

DIE CHEMISCHE TECHNOLOGIE DER BRENNSTOFFE. Von Prof. Dr. FERDINAND FISCHER. Dritte Lieferung. Friedrich Vieweg und Sohn, Druck und Verlag von, Brunswick. 1896. H. Grevel and Co., 33, King Street, Covent Garden, London. Price 5s.

THIS Part III. of the above work on the Chemical Technology of Fuel, presents the various problems of Thermo-Chemistry belonging to the subject, and then treats of Wood and Peat as articles of Fuel. The subject also of Coal is dealt with, and its Occurrence, Statistics, and Chemistry are treated very fully. A subsequent Part—Part IV.—is promised, which will deal with Compressed Fuel and the Coking Industry.

This number contains 185 pages of subject-matter, and is illustrated with 39 wood engravings.

RÉPERTOIRE DES REACTIFS SPECIAUX. Généralement désignés sous leurs noms d'Auteurs. En vente chez les Auteurs, FERDINAND JEAN et G. MERCIER. Published and sold by the Authors, the former at 17, Faubourg St. Denis, the latter at 158, rue Saint Jacques, Paris. 1896. Price 2 fr., or post free 2.25 fr.

In this little work, in which each alternate page is blank, those reactions and tests are given which are generally known by the names of their authors or discoverers. In the first part of the book the substances are given, alphabetically arranged, which form the subjects of the reactions, whilst in the second part, appear the descriptions of the reactions themselves arranged under the names of their discoverers, alphabetically given. The methods of preparing the tests are added, and frequently their degrees of sensitiveness. The alternate blank pages are for the entry of additional tests, errata, &c., and the authors cordially invite readers to forward to them any such addenda and errata, which they promise, as far as may be, to enter in their next edition. This present and first edition contains 121 pages, and is of a size suitable for the pocket.

LES NOUVEAUX CHIMIQUES. Nouveaux Appareils de Laboratoires, Méthodes Nouvelles de Recherches Appliquées à la Science et à l'Industrie. Par CAMILLE POULENC, D. ès Sc. Avec 62 figures intercalées dans le texte. J. B. Baillière et Fils, 19, rue Haute-Feuille, Paris. 1896. Price 2 fr. H. Grevel and Co., 33, King Street, Covent Garden, London.

THIS little work of small 8vo. size, and in paper cover, is devoted to summary descriptions of new laboratory apparatus and methods. It contains Preface, 131 pages of subject-matter, Table of Contents, and an Alphabetical Index, and its pages are illustrated with 62 engravings representing the more recently introduced apparatus and instruments, described therein.

The book contains five chapters. In Chapter I. general methods and apparatus are described, such as those concerned in Measuring Temperatures, Heating, Illumination, Distillation under ordinary Pressures and *in vacuo*. II. Treats of the various forms of Laboratory Apparatus and methods designed for or connected with certain kinds of Purification. III. Analysis under its more recent forms is here represented, and chiefly Lunge's Volumeter and its applications. IV. New Electro-Chemical Apparatus is the subject here considered and illustrated; and V. The more recent methods in Chemical Biology or Bacteriology.

CHEMISCH-TECHNISCHES REPERTORIUM. Uebersichtlicher Bericht über die neuesten Erfindungen, Fortschritte und Verbesserungen auf dem Gebiete der technischen und industriellen Chemie, mit Hinweis auf Maschinen, Apparate und Literatur. Herausgegeben von Dr. EMIL JACOBSEN, 34. Jahrgang. 1895. Zweites Halbjahr. Erste Hälfte. Mit in den Text gedruckten Illustrationen. Hermann Heyfelder, R. Gaertner's Verlagsbuchhandlung, Schönebergerstr. 26, Berlin, S.W. H. Grevel and Co., 33, King Street, Covent Garden, London.

THE first issue for the second half-year of 1895, of Dr. Jacobsen's Repertory of Chemical Technology, containing reports of the progress of the following branches of chemical industry:—I. Building Materials, Cements, &c. II. Dyestuffs, Dyeing, and Calico Printing. III. Fats, Oils, Illuminating and Heating Materials. IV. Fermented Liquors. V. Tanning, Leather and Glue Manufacture. VI. Textiles. VII. Glass and Earthenware. VIII. Wood and Horn. IX. India-rubber and Gutta-percha. X. Cements and Adhesives. XI. Lakes, Varnishes, and Paints. XII. Metals.

EXPERIMENTAL-UNTERSUCHUNGEN ÜBER ZERSETZUNG UND VERBRENNUNG VON KOHLENWASSERSTOFFEN. Habilitationsschrift zur Erlangung der venia legendi für Technische Chemie an der Grossh. Bad. Technischen Hochschule zu Karlsruhe. Von Dr. FRITZ HABER. R. Oldenbourg, Verlag, München. 1896. Price M. 1.50.

LARGE 8vo. volume in paper cover, containing 116 pages of subject-matter dealing with the subject of the Decomposition and Combustion of Hydrocarbons. The method of treatment of the subject may be derived from the following brief synopsis of the contents:—A. Decomposition of Hexane and Trimethylethylene by Heat. Measuring of Temperatures in Electric Tubular Furnaces. B. Combustion of Illuminating Gas on Cooled Surfaces and in Gas Motors. Experiments on the Fractional Combustion of Mixtures of Carbonic Oxide, Hydrogen, and Methane. Qualitative Determinations of the Combustible Portions of Heating Gas. Useful Effect of Gas Cooking-Apparatus. Experiments on Combustion in Gas Motors, &c. The work is illustrated with 19 wood engravings.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

FRANCE.

Tariff Decisions.

Board of Trade Journal, April 1896, 438.

A despatch, dated March 6 last, has been received from the Foreign Office, enclosing copy of a French Customs circular to the following effect:—

"Thorium salts, especially nitrate or azotate, solutions of which are employed in the preparation of incandescent gas-burners, belong to the class 'Chemical Products not denominated, other than of an alcoholic basis,' and pay a duty of 5 per cent. *ad val.* The estimation of the value of these products having given rise to many disputes, the Departments of Trade and Finance have decided to convert the duty of 5 per cent. into an equivalent specific rate, and considering that the value of thorium salts, once 2,000 frs. per kilo., is now only about 400 frs., on account of recent

discoveries of extensive deposits of thorium ore, it has been decided to substitute for the duty of 5 per cent. *ad val.*, a specific rate of 20 frs. per kilo."

NETHERLANDS.

Free Entry of Sulphuric Ether.

Board of Trade Journal, April 1896, 435.

A despatch, dated March 25 last, has been received at the Foreign Office from Sir Horace Rumbold, Her Majesty's Minister at The Hague, enclosing translation of a law published in the *Official Gazette* of March 25 last, by which sulphuric ether, used in the manufacture of gilding for the decoration of porcelain or earthenware, is exempted from import duties under certain conditions, which apply exclusively to the importer.

The translation of the above law is given in *extenso*.

BRITISH INDIA.

Board of Trade Journal, April 1896, 418.

Exemptions from Duty.

By Customs circular, dated February 14 last, and in exercise of the power conferred by section 23 of the Sea Customs Act, VIII. of 1878, the Governor-General in Council is pleased to exempt from import duty the articles in the subjoined list, when such articles are imported by the owner of a cotton-weaving mill, and are shown to the satisfaction of the collector to be intended for use in the weaving of cotton or the baling of woven cotton goods.

List of Articles to be Exempted.

Aniline blue, bisulphate of soda, china clay, chloride of magnesium, chloride of zinc, Epsom salts, farina, flannel, taping, Glauber salts, glutina, glycerin substitute, head varnish, hoop iron, rivets for bales, sewing needles, sizing paste, sizing wax, soda ash, starch.

CUSTOMS TARIFF OF GUATEMALA.

Section 15.

Drugs, Medicines, &c.

See Board of Trade Journal for April 1896, 430—434.

UNITED STATES.

Engineering and Mining Journal, March 21st, 1896, 282.

Duty on Metal Foils.

Zinc foils and a foil of which copper is the component material of chief value. Both were assessed at 35 per cent. under para. 177. The one was claimed to be dutiable under para. 175 as zinc in sheets not further advanced, and the other as copper in sheets under para. 161. The protest was overruled.—Lehmaier, Schwartz, and Co. v. Collector of the Port of New York: Board of United States General Appraisers.

Duty on Metallic Paints.

Metal red, alizarin colours and alizarin lakes, and ultramarine blue. All of them were assessed at 25 per cent. under para. 48. The metal red was claimed to be dutiable as vermilion red at 6 cents per lb., under para. 45; the alizarin colours to be free, under para. 368, and the ultramarine blue to be dutiable at 3 cents per lb. under para. 45. The assessment on metal red was affirmed; as to the alizarin colours and alizarin lakes and ultramarine blue, the protest was sustained.—R. F. Downing and Co. v. Collector of the Port of New York: Board of United States General Appraisers.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

PHARMACEUTICAL PRODUCTS IN THE PHILIPPINES.

Chamber of Commerce Journal, March 1896, 47.

The French Consul at Manila recommends prudence in commercial relations with native pharmacists, this now being more necessary than ever in consequence of the competition between French pharmaceutical products which

are more or less gross imitations, but of which the prices are very much lower. During the last decade the value of such imports into the Philippines has greatly diminished, although the Manila pharmacies are fuller than ever of medicaments of all kinds and of all origins. Germans have particularly made headway with quinine at "half-price," but in a condition of efficacy on which the Consul does not consider it necessary to comment.

GENERAL TRADE NOTES.

GERMAN TRADE IN SOUTH AFRICA.

Board of Trade Journal, April 1896, 402.

The figures of the South African trade are of particular interest. In the seven years from 1889 to 1895, the exportation of German manufactures to the Cape is valued at 3,000,000*l.*; to the Transvaal at 1,032,000*l.* In the year 1892 the exportation to both these countries amounted to no more than 395,000*l.* In 1895 it had risen to 1,056,000*l.* This exportation embraces various branches of industry, especially iron, machinery, textiles, and chemicals. Further important articles are sugar, beer, explosives, and leather goods.

In the last two years, for instance, the following goods have been exported:—

	Cwts.
Dyed cotton goods	8,250
Cyanide of potassium	2,200
Explosives	74,400
Beer, in bottles	32,510
Refined sugar	21,200

The increase in the exportation of cyanide of potassium is very noticeable, and this is due to its demand for use in the production of gold. The exportation of this article dates only from the year 1892. In that year 1,658 cwt. of the value of 11,372*l.* was exported to the Transvaal; in 1895 the exportation of this article had increased to 18,184 cwt. and 147,000*l.*

The development of the gold production of the Transvaal has given a great impetus to the export of this article, as is evidenced by the fact that whereas the whole German exportation of cyanide of potassium to the Transvaal in 1891 only amounted to 820 cwt., in 1895 it had reached the above figures.

THE MINERAL PRODUCTION OF ITALY.

The *Revista del Servizio Minerario*, recently issued, gives statements of the mineral production of Italy in the year 1894. The output of minerals from the Italian mines for the year was as follows, the quantities being in metric tons:—

Iron ore	187,728 tons
Manganiferous iron ore	5,810 "
Manganese ore	760 "
Copper ore	92,886 "
Zinc ore	131,777 "
Lead ore	29,822 "
Gold ore	7,748 "
Silver ore	1,103 "
Antimony ore	1,504 "
Quicksilver ore	15,022 "
Iron pyrites	22,638 "
Coal and lignite	271,294 "
Sulphur, raw	13,850 "
Sulphur, melted	391,931 "
Rock salt	19,467 "
Spring salt	11,326 "
Asphalt and bitumen	60,493 "
Petroleum, crude	2,854 "
Gaseous hydrocarbon	12,000 cb. m.
Alunite	6,006 tons
Boric acid	2,745 "
Graphite	1,570 "

The total value of the minerals at the mines is given as 52,042,605 lire (810,408,521*l.*). Nearly half this amount—25,267,955 lire, or 85,053,591*l.*—was furnished by the sulphur mined. The average value of the coal mined was 7 lire (81*l.* 40) per ton. The gold ore was of low grade, being rated only at 85 lire, or 817 *l.* per ton.

Included in the total values; but not given in the table, are mineral waters valued at 499,829 lire, or \$81,965, their amount being estimated at 21,730 tons.

The total number of men employed in and about the mines was 51,994. The average value per man employed was 1,001 lire, or \$200; but no statistics are given as to the time worked. The largest number, 30,339 in all, were at work in the sulphur mines. The lead and zinc mines employed 10,173 persons; the coal mines, 2,347; the iron mines, 2,178; and the copper mines, 2,003. No other industry employed over 1,000 men. In the production of gaseous hydrocarbon only one man was engaged.

The metallurgical products for the year 1894 were as follows in metric tons, except where otherwise noted:—

Pig iron	10,329 tons
Iron castings	10,060 "
Wrought iron	141,729 "
Steel	51,014 "
Roller plates	5,750 "
Copper and copper alloys	7,918 "
Zinc	280 "
Lead	19,605 "
Silver	58,926 kilos.
Gold	349 "
Antimony	351 tons
Quicksilver	258 "
Briquettes, mineral	599,754 "
" wood, peat, &c.	21,370 "
Sulphur, refined	35,659 "
Sulphur, powdered	90,561 "
Sea salt	192,515 "
Asphalt and bitumen	7,824 "
Petroleum, refined	1,640 "
Gas, lighting	148,982,553 cu. m.
Gas products, coke, tar, ammonia, &c.	433,399 tons

The total value of the metallurgical products was 165,211,633 lire (\$33,042,327), and the number of men employed was 22,558. Of these, nearly one-half, 11,084 in all, were engaged in the iron and steel manufactures. There were 2,913 men employed in the manufacture of salt and 1,455 in the preparation of sulphur. The gas industry required 3,590 men.

The average value of the zinc produced is given at 1,100 lire (about \$220) per ton. Silver is rated at 110 lire (\$220) per kilo., and gold at 3,608 lire (\$724) per kilo. Refined sulphur had an average value of \$1 lire (\$16.20) per ton. The average value of the products was 7,324 lire (\$1,465) per man employed. The data given, however, do not state the average working time.

PRODUCTION OF CAOUTCHOUC IN BRAZIL.

Board of Trade Journal, April 1896, 471.

The *Bulletin Commercial* states that, according to American statistics, the production of caoutchouc in the province of Para (Brazil), which is constantly on the increase, has doubled in the last 12 years, and quintupled in the last 30 years. The production of 1895 was 13.4 per cent. greater than that of 1894 and 10.2 per cent. greater than that of 1893.

The following statement shows the value of the exports in certain years:—

Years.	Value.
1865	8,243,000
1870	10,528,000
1875	15,114,000
1880	18,889,000
1885	29,310,000
1890	56,300,000
1895	103,303,000

The imports of caoutchouc into the United States have increased in about the same proportion as the exports from Brazil, but in 1895, for the first time, the amount of caoutchouc sent from Para to Europe was greater than that sent to the United States. The increase is specially noticeable in England, France, and Germany, where Para caoutchouc is in great demand.

THE MINERAL PRODUCTION OF CANADA, 1895.

Engineering and Mining Journal, March 14th, 1896, 254.

Through the courtesy of Mr. E. D. Ingall, of the Geological Survey of Canada, we are enabled to publish the preliminary statistical table of the mineral production of Canada. Some of these returns are estimated, but the usual care under the direction of Dr. G. M. Dawson, head of the Department, ensures a very close approximation to the ultimate figures:—

Product.	Quantity (a).	Value (a).
METALLIC.		
Copper (b)	Lb. 8,789,162	Dols. 994,220
Gold	Fine oz. 92,448	1,916,921
Iron ore	Tons 102,797	238,070
Lead (fine, in ore, &c.) (c)	Lb. 23,075,892	749,966
Mercury	" 230	2,343
Nickel (fine, in ore, &c.) (d)	Lb. 3,888,526	1,360,984
Silver (fine, in ore, &c.) (e)	Oz. 1,775,683	1,158,633
Total metallic	"	6,370,146
NON-METALLIC.		
Asbestos	Tons 8,756	368,175
Baryta	" 8	168
Chromite	" 3,177	41,391
Coal	" 3,512,504	7,774,178
Coke (f)	" 53,356	143,047
Fire-clay	" 1,329	3,192
Graphite	" 220	6,150
Grindstones	" 3,919	31,532
Gypsum	" 236,178	202,998
Limestone for flux	" 31,579	32,916
Manganese ore	" 125	8,464
Mica	"	65,000
Ochres	Tons 1,339	1,690

67	Quicksilver.....	Flasks, 76½ lbs.	30,140	1,056	1,095,840	33,378	1,179	1,313,589
68	Silver, commercial value.....	Troy Ounces	49,849,875	1,556,387	31,463,531	46,331,235	1,441,087	30,254,296
69	Zinc, spelter.....	Short Tons	74,004	67,135	5,299,882	81,858	74,215	5,942,890
Total metals.....			194,092,119	240,615,120
Estimated products unspecified.....			5,000,000	5,000,000
Grand total.....			578,463,002	673,689,505

(a) Bituminous coal includes brown coal and lignite. The anthracite production is the total for Pennsylvania, Arkansas, and Colorado.

(b) Estimated.

(c) Kilograms.

BOARD OF TRADE RETURNS.

SUMMARY OF IMPORTS.

Articles.	Month ending 31st March.	
	1895.	1896.
	£	£
Metals.....	1,379,370	1,580,956
Chemicals and dyestuffs.....	885,527	953,968
Oils.....	680,297	581,593
Raw materials for non-textile industries.....	5,131,237	5,330,295
Total value of all imports.....	35,069,890	38,544,750

SUMMARY OF EXPORTS.

Articles.	Month ending 31st March.	
	1895.	1896.
	£	£
Metals (other than machinery)....	2,229,136	2,684,456
Chemicals and medicines.....	739,269	867,574
Miscellaneous articles.....	2,767,391	2,931,066
Total value of all exports.....	18,523,690	20,422,419

IMPORTS OF METALS FOR MONTH ENDING 31ST MARCH.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

5833. J. D. Morel. Improvements in mechanism for cleaning wool, cotton, and other fibrous substances. Complete Specification. March 16.

5849. F. H. Tyacke and C. E. Gittins. Improvements in water softening and purifying apparatus. March 16.

6210. S. T. Wellman and C. H. Wellman. Improvements in apparatus for charging metallurgical and other furnaces. March 20.

6318. J. F. Lester. Improvements in apparatus for treating vegetable and animal fibre with solvents. Complete Specification. March 21.

6377. D. Adorjan. Improved method and apparatus for producing highly overheated steam and vapour. March 23.

6749. H. Krack. Improvements in cooling apparatus for liquids. Complete Specification. March 27.

6785. H. L. Doulton. Improvements in condensing worms constructed of pottery. March 28.

6934. F. Jurschina, Z. Schnitzer, and F. Hersch. An improved filtering material and process of making the same. March 30.

7251. L. M. G. Delaunay-Belleville. Improvements in distilling apparatus for the production of fresh or drinking water. Complete Specification. April 2.

7335. P. S. U. Pickering. An improved evaporimeter. April 4.

7802. A. T. Pfeiff. Improvements in apparatus for sterilising milk, cream, and other liquids by means of steam. Complete Specification. April 13.

7868. T. C. Sanderson. Improvements in apparatus for drying white lead, colours, and other powdery, granular, and nodular substances. April 14.

7878. W. R. Jones. Improvements in furnaces. Complete Specification. April 14.

7913. E. Johnson and J. Thompson. Improvements relating to gas-regenerative furnaces. April 15.

7997. W. Shedlock. Improvements in and relating to evaporating apparatus, chiefly designed for obtaining salt from brine. April 15.

8198. A. S. Bryce, jun. Improvements in packing for hydraulic apparatus. Complete Specification. April 15.

COMPLETE SPECIFICATIONS ACCEPTED.*

1895.

6231. H. Nehmer and F. Nehmer. Improvements in statical machines for lighting gas, ether, benzoline, and such like. March 25.

6491. J. Lee. Evaporating apparatus. April 1.

9395. C. H. Wild. Improvements in certain hydraulic presses for pressing fabrics. March 25.

10,571. E. Theisen. Improved method of and apparatus for evaporating, condensing, and cooling fluids. April 15.

11,039. J. Humes. Gas compressors. April 8.

11,405. C. Pottier. An improved basket or packing-case for carboys of acid and the like. April 15.

1896.

3345. J. Laidlaw and J. W. Macfarlane. Improvements in centrifugal machines for separating fluids of different densities. April 8.

3569. E. Petzholtz. Improvements in or connected with furnaces. March 25.

3668. T. Jenkins. Hydro-extractors. March 25.

4253. E. C. Nichols. Apparatus for compressing and storing air. April 8.

4418. H. H. Lake.—From W. F. Jobbins and J. van Ruymbeke. Evaporating apparatus. April 22.

4604. E. Theisen. Apparatus for evaporating, condensing, and cooling fluids. April 22.

5109. S. Pitt.—From La Compagnie Internationale des Procédés A. Seigle. An automatic re-ignition apparatus for hydrocarbon furnaces. April 15.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

5786. H. A. Kent. An apparatus for the utilisation or efficient burning of small or dust coal and other fuel in ordinary fire grates. March 16.

5790. P. R. de Fauchaux d'Ilumy. Improvements in the manufacture of fuel. March 16.

5796. P. R. de Fauchaux d'Ilumy. Improvements in the manufacture of briquettes for use as fuel or the like. March 16.

5813. T. Holliday. Improvements in means or apparatus for use in the production and application of acetylene gas. March 16.

5905. G. Webb and J. W. Kelly. Automatic gas-generator. March 17.

5916. F. A. MacKinnon. A new or improved method or process for the treatment of coke so as to render it suitable for transport. March 17.

5976. E. Appleby and H. F. Harris. An apparatus for automatically and safely generating and storing acetylene. March 17.

5984. W. W. Holmes. Improvements in the manufacture of artificial fuel. March 17.

5989. T. M. Ash and H. N. Weldon. Improvements in the manufacture of mantles for use in incandescent gas-lighting. March 17.

6008. F. S. Cripps. Improvements in apparatus for evaporating oil or other liquids, and mixing the vapours produced with coal-gas. March 18.

6254. W. Parlbj. Improvements in apparatus for quenching or cooling coke produced in the manufacture of coal-gas. March 20.

6349. H. Hart. Improvements in or relating to illuminating apparatus. March 23.

6380. Sir E. Green, Bart. Improvements connected with fuel economisers. March 23.

6408. A. Sweetser. Improvements in and connected with apparatus for the manufacture of oxygen gas. March 23.

6719. R. Reitmeyer. — From A. Cerekel. Improved apparatus for lighting and heating by means of acetylene. March 27.

6739. J. C. Bayley. Improvements in apparatus for generating and storing acetylene gas, especially suitable for use in portable installations. March 27.

6852. H. C. B. Forester. Improvements in and in apparatus for pressing artificial or patent fuel or the like into solid form. March 28.

6853. H. C. B. Forester. Improvements in apparatus for manufacturing artificial or patent fuel. March 28.

6857. G. Hilgenstock. Improvements in coke ovens. March 28.

6919. J. E. Dowson. Improvements in apparatus for making combustible gas. March 30.

6922. V. B. Lewes. Improvements in the manufacture or production of illuminating gas. March 30.

6930. J. C. Mcburn. — From A. C. Fraser. Improvements in the treatment of acetylene for illuminating and other purposes. March 30.

6999. A. Hussener. Improvements in horizontal coke ovens. Complete Specification. March 31.

7082. A. G. Wild. Improvements in apparatus for the production of acetylene gas for use upon railway carriages and other vehicles and places. April 1.

7085. W. Wardle. An improved method of manufacturing fuel from refuse and various waste substances. April 1.

7226. G. G. Schroeder. Improvements in gas-enriching apparatus. Complete Specification. April 2.

7242. W. C. Clarke. Method of and apparatus for generating acetylene. Complete Specification. April 2.

7243. W. C. Clarke. Method of generating illuminating gas. Complete Specification. April 2.

7286. C. Billington, jun. An improved method of and means for removing "scum" or "retort carbon" from gas retorts. April 4.

7367. H. Hill. Improvements in mantles or hoods for incandescent gas lights. April 7.

7429. J. B. de Lery. Improvements in and relating to mantles for incandescent gas and oil lamps. Complete Specification. April 8.

7438. E. H. C. Ochlmann. Improvements in incandescent gas burners. April 8.

7463. L. Denayrouze. Improvements in incandescent gas lighting. April 8.

7477. P. Schroeder. Improvements in incandescence gas burners. Complete Specification. April 8.

7559. W. Hampson. Apparatus for separating mixed gases by refrigeration, especially applicable to the separation of oxygen from air. April 9.

7624. A. Guaseo. Improvements in means and process for purifying and utilising the gases and other volatile products resulting from combustion. April 10.

7693. P. Woog. Improvements in or relating to lamps and apparatus for the generation and combustion of acetylene gas. April 11.

7869. H. A. Kent. Improvements in combined apparatus for generating, accumulating, and regulating a constant supply of acetylene gas. April 14.

7901. J. M. Mitchell. Apparatus for mixing air and gas. Complete Specification. April 14.

8005. W. Irwin. An improved method for the extraction of cyanides from coal-gas. April 16.

8098. W. H. Hill-Hartland. Improvements in treating furnace gases for re-use and consumption of smoke, and in means or apparatus therefor. April 17.

8161. W. Tyree. Improvements in or relating to the combustion of fuel. April 17.

8239. C. Gautzsch. Improvements in apparatus for producing illuminating gas. Complete Specification. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6615. H. H. Lake. — From M. M. Rotten and Co. Treatment of peat and apparatus therefor. April 8.

9739. D. W. Stone and B. Chaplin. An improved method of and apparatus for the treatment of smoke. April 1.

10,129. H. Reeser, jun. Improvements in the manufacture of mantles or luminous bodies for incandescent gas lamps and in compounds for use in such manufacture. April 1.

10,477. J. H. Ladd. Improvements relating to the manufacture of gas and to apparatus therefor. April 1.

10,697. W. Fiddes. Apparatus for discharging gas retorts. April 22.

11,039. J. Humes. See Class 1.

11,820. H. Gardner. — From La Société Française de l'Héliogène. Improved method of combining air and gas for incandescent lighting purposes. April 22.

12,020. S. Hersey and Kirkham, Hulett, and Chandler, Lim. Apparatus for washing or scrubbing gas. April 1.

16,691. R. Campe. An improved generator for acetylene gas lamps. April 15.

19,202. S. H. Crocker. Mantles for incandescent light. April 8.

1896.

2000. C. Kortwich. Glow bodies for incandescent gas lighting. April 8.

4192. A. Morgan. Improvements in gas heating and lighting. April 15.

4421. J. Anderson. — From W. Anderson. A shield for an incandescent gas mantle. April 1.

5375. E. T. Turney. Improvements relating to the generation of gas and to apparatus therefor. April 22.

5624. E. Farnsworth. Apparatus for the manufacture of gas. April 22.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

14,617. C. H. McEwen. — From J. C. Alexander and R. C. Beveridge. Improvements in the treatment of kerosene shale for the production of hydrocarbons and other products therefrom. April 8.

1896.

4598. A. Schmidt. Apparatus for the dry distillation of wood, coal waste, and the like. April 8.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

5857. H. H. Lake. — From Farbwerk Mühlheim. Improvements in the manufacture of colouring matters. March 16.

5858. H. H. Lake.—From Farbwerk Mülheim. Improvements in the manufacture of colouring matters and raw materials for use in such manufacture. March 16.

7043. G. H. Weiss. The manufacture of a new colour-producing aromatic diamine. Complete Specification. March 31.

7313. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of new raw materials and of direct-dyeing colouring matters derived therefrom. April 4.

7538. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of anthracene compounds and of dyestuffs derived therefrom. April 9.

7596. Levinstein, Lim., and I. Levinstein. Manufacture or production of new colouring matters. April 10.

7597. Levinstein, Lim., and I. Levinstein. Production or manufacture of new colouring matter. April 10.

7709. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new derivatives of amido-1 alhyl-2 alkyl-5 pyrazolones. April 11.

7766. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. The manufacture and production of new colouring matter from dinitro-naphthalene. April 13.

7788. O. Imray.—From G. H. Weiss. Manufacture of colouring matters from carbamides or thioearbamides. April 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

9794. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs and materials therefor. March 25.

10,668. H. H. Lake.—From Farbwerk Mülheim. Manufacture of colouring matters. April 8.

10,676. J. Y. Johnson.—From The Chemische Fabrik vormals Goldenberg, Geromont, and Co. A process for obtaining the acetyl derivatives of methyl-aniline, ethylaniline, para-anisidine, and para-phenetidine. April 1.

11,228. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of new azo dyestuffs. April 15.

11,276. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs suitable for dyeing cotton. April 15.

11,757. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of chemical compounds suitable for the production of colouring matters in bulk or on fibre. April 22.

11,843. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs. April 22.

12,221. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of colouring matters dyeing yellow with mordants. April 8.

12,303. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. The manufacture and production of poly-azo dyes of the benzidine and analogous series. March 25.

12,442. Brooke, Simpson, and Spiller, Lim., and W. S. Simpson. Improvements in colouring matters. April 1.

12,529. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Improvements in the manufacture of azo colouring matters. April 15.

13,032. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. Improvements in the production of blue, bluish-black, or greenish-black poly-azo dyes on vegetable fibre or on silk. April 1.

13,460. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. The manufacture and production of new nitrosamine compounds suited for use in the preparation of diazo compounds and of azo dyes. March 25.

14,135. J. Y. Johnson.—From The Badische Anilin and Soda Fabrik. The manufacture and production from phthalonic acid of products related to the rhodamine series. April 1.

1896.

5268. O. Imray.—From The Society of Chemical Industry in Basle. Process for the transformation of the thiosulphonates of the indamines and indo phenols into thiazine colouring matters. April 15.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

6519. J. Ingleby and E. Osclere. Improvements in or in connection with the manufacture of linoleum, cork carpets, and the like fabrics, and in machinery or apparatus therefor. March 25.

6527. J. L. Bortomley. Improvements in the manufacture of yarns. March 25.

7405. C. Efros. Improvements in the treatment of vegetable fibres. Complete Specification. April 7.

8235. J. Weiss. A chemical process for the production of white or coloured crape-like designs on cotton, linen, or other fabrics or yarns of vegetable origin. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

16,399. E. Nelson. Manufacture of fibrous bituminous felt. April 8.

24,586. L. Schmiewind and A. Schmidt. Improvements in elastic woven textile fabrics. April 1.

1896.

2213. J. C. Anderson. Improvements in and relating to process of and apparatus for the treatment of wool. April 8.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

5901. A. A. Kuenemann and F. D. Haddon. Improvements in the production of printed designs upon fabrics and in apparatus to be employed therefor. March 17.

6028. E. Deakin. Improvements in kiers for bleaching and similarly treating textile fabrics and other materials. March 18.

7610. T. Lye and W. T. Lye. Improvements in the bleaching or dyeing of chip-chip plait, straw, or straw plait. April 10.

7977. H. W. V. Wilson and W. Brown. Improvements in or relating to apparatus for varnishing or otherwise coating paper, cardboard, or other material. April 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

10,424. R. W. E. McIvor and J. Chester. Improvements in the mode of bleaching reed, ramie, china grass, and other vegetable fibres and undyed fabrics made from vegetable fibres. April 1.

10,716. F. Stehle. See Class XIX.

20,153. T. F. Hassler. An improved process for dyeing and drying yarn. March 25.

21,511. L. Mistoviki. Improvements in the production of ornamental and other designs upon waterproof, textile, and other fabrics. April 8.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

6096. D. A. Peniakoff. Improvements in the manufacture of aluminate of barium and aluminate of strontium, and the production of alumina sulphate of barium and of strontium and other products from the same. March 18.

6270. J. S. Pattinson and Fawcett, Preston, and Co., Lim. Improvements in the treatment of certain earths for the extraction of the soluble matters therefrom. March 21.

6290. D. Peniakoff. See Class X.

6808. F. Bale. Improvements in obtaining the vapour of ammonium chloride alone or mixed with either of its constituent gases (NH_3 or HCl) and obtaining therefrom ammonia and hydrochloric acid, or chlorine, and in the apparatus used. March 28.

6835. B. T. L. Thomson. Improved process and apparatus for the manufacture of carbonic acid gas. March 28.

6856. C. M. Lévy. The manufacture of a washing and bleaching composition. March 28.

6887. R. Addie. Process for extracting cyanides from blast-furnace dust or other crude salts and aqueous solutions containing cyanides. March 30.

7002. H. H. Lake.—From L. Sternberg. Improvements in and relating to the production of ammonia from waste products, such as the waste lyes resulting from the extraction of sugar or the manufacture of alcohol from molasses. Complete Specification. March 31.

7062. A. C. Thomson. Improvements in apparatus for obtaining potassic cyanides. April 1.

7123. A. von Siemens. Process for working metallic sulphides. Complete Specification. April 1.

7124. O. Imray.—From La Société Christiania Minekompani. Process for the production of ammonia and ammoniacal salts, as also nitrous or nitric acid or nitrites or nitrates, by means of the nitrogen of atmospheric air, or of that contained in combustion gases of any kind. April 1.

7464. A. MacNab. An improvement in the treatment of hay salt. April 8.

7796. W. Shedlock. Improvements in and relating to apparatus for obtaining salt from brine and for similar purposes. April 13.

7910. J. Plummer. Process to obtain ammonia and hydrochloric acid from ammonia chloride. April 15.

7969. J. Enright. An improved method of manufacturing sulphurous anhydride and its derivatives, and apparatus therefor. April 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

7560. C. Hoepfner. Improvements in the manufacture of chloride of zinc and other metal chlorides, applicable also to the manufacture of acetate or sulphate of zinc. April 1.

9332. T. Twynam. Improvements in the fixation of nitrogen and the production of cyanides. March 25.

10,713. R. Main and W. Donald. Improvements in treating chlorides for the production of chlorine and alkalis or alkaline earths, and the recovery of by-products. March 25.

10,931. O. Imray.—From Goerlich and Wichmann. Process for decomposing sulphuretted hydrogen and obtaining ammonia, compounds of ammonia, oxysulphides, sulphides, and sulphur. April 1.

23,819. R. Main and W. Donald. Improvements in treating nitrates for the production of nitric acid, and the recovery of by-products. March 25.

1896.

3987. W. P. Thompson.—From C. von der Linde. An improved process for obtaining acetic acid from pyro-ligneous salts. March 25.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

7305. T. Reeves. A novel method of applying the art of portraiture to pottery, glassware, and turnery, and of producing some special effects thereby. April 4.

7899. R. Stanley. Improvements in ovens for drying and burning tiles, pottery, and other plastic or semi-dry ware. April 14.

8148. The Coalport China Co. (J. Rose and Co.), Lim., and T. J. Bott. Improvements in or connected with the ornamentation or decoration of china, earthenware, glass, and like ware. April 17.

COMPLETE SPECIFICATION ACCEPTED.

1895.

11,595. J. L. Rawdon and The British and Foreign Patent Syndicate. Improved composition for use in the plastic arts. April 22.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

6232. F. L. Schauermaun and J. S. Cowper. An improved composition for use in imitation of or in substitution for wood. March 20.

7023. O. J. Owen. Improved manufacture of cement or plaster. March 31.

7032. A. M. Clark.—From The Electric Fireproofing Co. Method and apparatus for treating wood. March 31.

7567. W. C. Lawton. Improvements in the process of manufacturing ornamental strips of soft clay. April 9.

7866. J. Hamblet and I. Parkes. Improvements in or additions to machinery used in the manufacture of coping bricks, terra-cotta building blocks, and the like. April 14.

7892. J. E. Summers and J. H. Ogburn. Improvements in plastering compounds. April 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6866. P. Stolte. Improvements in building slabs or blocks. April 8.

9876. H. H. Leigh.—From F. A. Jumeau. Improvements in and connected with the manufacture of pictures in cement or analogous material. March 25.

10,089. J. Patchett. Time precipitation process of mortar analysis. April 22.

10,090. J. Patchett. Measure process of mortar analysis. April 22.

10,468. A. Roberts. A new or improved substitute for tiles for the coverings of walls, ceilings, and other suitable places. April 15.

11,688. A. W. Lundberg, J. O. Hallgren, and V. F. L. Smidth. Improvements in kilns for burning Portland cement, Roman cement, or other hydraulic cements or lime. April 8.

23,880. P. Jantzen. An improved method of and apparatus for making artificial stone blocks or plates. March 25.

1896.

3985. A. Clery. A new or improved cement. March 25.

4918. R. A. Chesebrough. Improvements in the art of manufacturing cement. April 22.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

5781. S. O. Cowper-Coles. Improvements in and apparatus for applying zinc or other metallic coatings to iron, steel, or other surfaces. March 16.

5845. J. B. Torres. Improvements in or relating to the extraction of gold and other gold metals from ores and the like. March 16.

6009. J. Hill. Improved composition of furnace bottoms for heating iron or steel. March 18.

6033. W. Pearson and J. A. Bott. Improvements in the manufacture of aluminium alloys. March 18.

6242. J. Mait. Apparatus for separating and saving gold. Complete Specification. March 20.

6290. D. Peniakoff. A process for the production of double aluminium sulphides (or sulphurets) with alkaline metals or metals of (the nature of) alkaline earths. Complete Specification. Filed March 21. Date applied for Oct. 22, 1895, being date of application in France.

6473. H. R. Angel. Improvements in the treatment of refractory or other ores. March 24.

6572. J. Inray.—From M. A. J. Roux. Apparatus for separating volatile metals from their alloys. March 25.

6654. A. Karyscheff and S. Demmenie. A new pyrochemical process and apparatus for the direct production of iron and other metals from their ores. March 26.

6701. D. C. Dalzell. An improved process of annealing steel. March 27.

6712. J. Ruffle. An improvement in protecting the surface of the molten metal from the action of air when coating iron in a solid state, or steel in a solid state, with tin or the alloys of tin. March 27.

6713. J. Ruffle. An improvement in protecting the surface of the molten metal from the action of air when coating iron in a solid state, or steel in a solid state, with lead or the alloys of lead. March 27.

6714. J. Ruffle. An improvement in protecting the surface of the molten metal from the action of air when coating iron in a solid state, or steel in a solid state, with tin or the alloys of tin. March 27.

6744. J. G. Daw. An improved method and means for introducing solid or liquid reagents or other materials into molten metals. March 27.

6779. A. de Courey Scott. An improved process and apparatus for treating ore containing gold or silver, or both. March 27.

6921. O. Frolich. Process and apparatus for the extraction of metals from their ores by means of chlorine gas. March 30.

7272. F. B. Last and J. R. Wright. Improvements in the manufacture of steel. Complete Specification. April 1.

7273. D. A. Peniakoff. A process for the manufacture of double sulphides, or double compounds of sulphuret of aluminium with other sulpho-metal or metallic sulphides. Complete Specification. April 4.

7315. J. E. Preston. Improved amalgamating apparatus. Complete Specification. April 4.

7358. H. L. Haas. Improvements in process of nickel plating. Complete Specification. April 7.

7422. R. A. Hadfield. Improvements in the manufacture of steel or alloy of iron. Filed April 7. Date applied for Feb. 17, 1896, being date of application in United States.

7424. J. B. Torres. Improvements in or relating to the extraction of gold and other metals from ores and the like, and in apparatus therefor. April 8.

7436. W. Gibbings. Improvements in blast furnaces. April 8.

7447. H. R. Angel. The recovery of zinc from refractory ores. April 8.

7615. R. Farley and F. Tonks. Improvements in the manufacture of steel and iron sheets. April 10.

7745. W. H. Browning and J. G. Heywood. Improvements in the process of casting partly chilled objects and in means therefor. April 13.

7776. A. Tanxe. A new or improved process for hardening iron, steel, and other hard metals. Complete Specification. April 13.

7783. W. P. Thompson.—From E. Wohlwill. An improved process for obtaining chemically pure gold from fine gold and alloys rich in gold. April 13.

7816. W. Trewitt. Improvements in steel reheating furnaces. April 14.

7941. J. A. Mays. Improved method and apparatus for hardening and tempering steel plates. April 15.

8042. J. B. Torres. Improvements in and connected with the metallurgical treatment of gold and other ores, and in apparatus therefor. April 16.

8064. T. Huntingdon and F. Heberlein. Improvements in the treatment of sulphide ores of lead, zinc, or antimony, preparatory to smelting the same, and incidentally in obtaining sulphurous acid. April 16.

8072. W. T. Whiteman.—From The Compagnie Générale l'Alumine Exploitation des Brevets F. Raynaud (Société Anonyme). A new or improved process for the treatment of aluminous ores and silicious matters. April 16.

8226. W. S. Simpson. Improved means and apparatus for tempering or hardening metal articles. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

1894.

24,861. T. Parker. Improvements in the treatment of ores known as sulphide ores, for the separation and obtainment of the metals contained therein. March 2.

1895.

10,399. J. J. Christmas. An improved process for the treatment of gold-bearing antimony ores. April 22.

12,102. A. de Courey Scott. Improved process and apparatus for treating ores and liquors containing gold or silver, or both. April 22.

17,143. E. Smith. Improved process or method of producing brilliant effects upon bright metallic surfaces. April 15.

1896.

1146. L. Doig.—From Russel and Erwin Manufacturing Co. An improved method of preparing metal and metal articles for stamping and drawing in dies. April 1.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

6071. W. Rowbotham. Improvements in primary electric batteries. March 18.

6216. C. H. Parker and J. Pullman. Improvements in and relating to the treatment of sodium and potassium chlorides by electrolysis. March 20.

6407. W. S. Rawson. Method and apparatus for electrically coating articles with zinc. March 23.

6509. L. Epstein and F. Marza. A process and apparatus for decomposing sodium or potassium chloride and generating electricity. March 24.

6655. The Chemical and Electrolytic Syndicate, Limited, O. J. Steinhart, and J. L. F. Vogel. Improved process of producing basic lead carbonate and obtaining certain by-products. March 26.

6981. J. Entwisle.—From S. N. Smith and E. S. Baring-Gould. Improvements in electric batteries. Complete Specification. March 31.

7000. L. Epstein and F. Marza. A process and apparatus for decomposing sodium or potassium chloride and generating electricity. March 31.

7162. A. J. Boulton.—From J. Julien. Improvements in or relating to secondary batteries. April 1.

7174. J. C. Green. A metal for heating by electricity. April 2.

7222. A. S. Elmore.—From J. O. S. Elmore. Improvements in apparatus for manufacturing tubes by electrolytic deposit. April 2.

7255. H. H. Lake.—From J. Julien. Improvements in secondary batteries. April 2.

7259. W. P. Thompson.—From J. Julien. Improvements in and in the construction of soluble-metal electrodes for accumulators. April 2.

8080. E. Commaelin and R. Viau. An improved electrical accumulator under pressure. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6565. H. Tec. Improvements connected with the electrolysis of chlorides and other salts, and the evaporation of brine and other solutions. April 1.

6565A. H. Tee. Improvements connected with the electrolysis of chlorides and other salts, and the evaporation of solutions. April 1.

8306. C. P. Shrewsbury, F. L. Marshall, J. Cooper, and J. L. Dobell. Improvements in or connected with electric batteries. April 1.

8373. W. S. Rawson. Improvements in conductors for coupling cells of voltaic batteries. March 25.

8876. C. P. Shrewsbury, F. L. Marshall, J. Cooper, and J. L. Dobell. Improvements in or connected with electric batteries. April 8.

10,448. L. Falero and H. Lumley. Improvements in secondary or storage batteries. April 15.

11,016. H. Blackman. Improvements in electrolytic decompositions, and especially in the electrolytic production of bleaching agents and their uses, and in electrodes and apparatus therefor. April 8.

11,032. T. Eremin. Secondary batteries or accumulators. April 8.

11,298. E. Jordis. An improved method or process for obtaining metals or metallic alloys by electrolysis. April 22.

11,659. J. T. Niblett. Improvements in elements for secondary batteries. April 15.

23,852. S. S. Bromhead.—From La Société Anonyme des Anciennes Salines domaniales de l'Est Actien Gesellschaft. Diaphragms or partitions for electrolytic purposes formed of carbonates of alkaline earths. April 22.

24,837. P. Jensen.—From H. C. F. Stormer. Improvement in the method and apparatus for washing alkali amalgam obtained in electrolytic apparatus. April 15.

1896.

477. C. N. Stewart. Electrical storage accumulators. March 25.

5098. G. B. Baldo. Electrolytic processes and apparatus therefor. April 22.

XII.—FATS, OILS, AND SOAP.

APPLICATIONS.

5791. P. R. de Fauchaux d'Humy. Improvements in or relating to the production of lubricants. March 16.

5792. P. R. de Fauchaux d'Humy. A new or improved manufacture of soap. March 16.

6558. E. Benz. Improvements in soap. March 25.

7269. The Fish Utilisation Syndicate, Lim., and J. C. W. Stanley. Improvements in or relating to the liberation or recovery of oils and the like. April 2.

7379. W. R. Harrison and E. Stephenson. Improvements in the method of and apparatus for extracting oil from seeds or other oleaginous substances. April 7.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

7442. A. Lubn. A new or improved soap extract and a process for manufacturing the same. April 15.

9153. G. Mitchell. A new or improved process for the treatment and refining of vegetable oils during or subsequent to their expression from nuts, beans, seeds, and the like. March 25.

1896.

2896. J. Stockhausen. A new or improved soap. April 8.

3312. W. Hanley. Manufacture of soft and other soaps. April 8.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

APPLICATIONS.

6393. F. Spiller. Manufacture of multi-coloured or marbled natural or artificial ambers and process therefor. March 23.

6396. K. Thon. Improvements in blacking for leather and the like. Complete Specification. March 23.

6453. G. Wendler. Improvements in and relating to farinaceous and resinous solutions and mixtures. March 24.

6830. W. J. Clapp and F. S. Dauncey. Improvements in the manufacture of india-rubber and in machinery and apparatus therefor. March 28.

7537. P. Cannell-Benn and W. Barrett. Improvements in and connected with the production of pigments. April 9.

7785. J. Sanders. A new or improved composition applicable for covering or protecting ships' bottoms and other structures. April 13.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

9891. H. R. Gregory. Improvements in the manufacture of sulphate of lead and lead pigments. April 22.

10,715. J. H. R. Paterson. Improvements in treating gutta-percha or its compounds for the manufacture of golf balls and other goods. April 8.

17,108. J. F. Cobbledeik. Improved paint or composition for use on metal, wood, stone, or other substances. April 15.

1896.

4249. W. P. Thompson.—From C. S. Bailey. Improvements in compositions or compounds for removing paint. April 1.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

6209. P. H. Riemer. Chalk glue for all applications on wood, paper, and cardboard, and for all other purposes where glue is employed. March 20.

6323. C. Marter and M. J. Myers. An improved rapid process of tanning skins without acids. March 21.

6410. W. L. Wise.—From Knoll and Co. Improvements in the manufacture or production of an albumen tannin compound. Complete Specification. March 23.

7886. V. Gallien. Improvements in the process of and means for tanning hides. April 14.

XV.—AGRICULTURE AND MANURES, Etc.

APPLICATIONS.

6289. E. Paternotte. Chemical manure mixer. March 21.

6405. N. F. B. de Mercey. Improvements in the manufacture of manure. March 23.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

5844. J. Kantorowicz. An improved process for preparing soluble starch. Complete Specification. March 16.

5953. C. F. Kastengren. An improved method of purifying molasses, syrup, or other solution of sugar. Complete Specification. March 17.

6508. W. Feld. Process for the extraction of sugar from molasses and other saccharine liquors by means of barium hydroxysulphide, and the regeneration of the latter from the by-products produced. March 24.

7337. J. Perichon. Improved method and apparatus for the treatment of bagasse. Complete Specification. April 4.

COMPLETE SPECIFICATION ACCEPTED.

1896.

3565. M. Zahn. Sugar refining. March 25.

XVII.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

5960. A. B. White. An improved appliance for saving beer workings. March 17.

6147. F. B. Pike. An improved method of treating brewers' and distillers' grains. March 19.

7971. S. Pratt. A method of utilising brewers' grains. April 15.

8122. E. Müller and C. Müller. Process for clarifying beer and making it keep. April 17.

COMPLETE SPECIFICATION ACCEPTED.

1895.

8123. W. P. Thompson.—From J. Effront. An improved process for the fermentation of worts which have been rendered antiseptic. April 22.

XVIII.—FOODS, SANITATION, &c., AND DISINFECTANTS.

APPLICATIONS.

A.—Foods.

6596. W. Nageli. An improved process for sterilising and preserving food products and beverages. March 24.

6647. H. M. Myers and J. T. Myers. Improvements in milk sterilisers. March 26.

6920. C. L. Villar. Improvements in the preservation of meat. Complete Specification. March 30.

7042. H. Higgins. Improvements in or relating to the preservation of foods and other perishable goods. March 31.

7480. A. J. Boulton.—From F. Fritzsche and Co. Improvements in or relating to the preservation of organic substances. April 8.

7880. R. Haddan.—From Kathrein's Malzkaffee Fabriken mit beschränkter Haftung. Improvements in the process for producing coffee substitutes from grain. Complete Specification. April 14.

7894. J. H. Kellogg. An improved alimentary product and process of making the same. Complete Specification. April 14.

8152. A. Huber. Process for preserving eggs. Complete Specification. April 17.

8194. J. C. Uhlenbrock. Improvements in the method of and apparatus for the manufacture of margarine or butter substitute. Complete Specification. April 18.

8232. H. Higgins. Improvements in or relating to the preservation of foods and other perishable goods. April 18.

8233. H. Higgins. Improvements in or relating to the hermetic sealing of vessels. April 18.

B.—Sanitation.

5955. W. E. Adeney and W. K. Parry. The utilisation of by- and waste products from iron and steel industries for the manufacture of improved precipitants for the purification of sewage and other waste liquids. March 17.

6132. H. B. Sharp. Improvements in the manufacture of materials or compounds for use in the treatment of sewage and impure waters. March 19.

7268. The Fish Utilisation Syndicate, Ltd., and J. C. W. Stanley. Improvements in or relating to the treatment of fish and other offal or similar refuse. April 2.

8227. W. D. Scott-Moncrieff. Improvements in or relating to the treatment of sewage and other organically contaminated liquids, and in apparatus therefor. April 18.

C.—Disinfectants.

5793. P. R. de Fauchaux d'Ilumy. Improvements in disinfectants or antiseptics. March 16.

5955. W. E. Adeney and W. K. Parry. See Class XVIII. B.

7333. H. H. Lake.—From Soc. Anonyme de la Fab. de Carton de Grandson et d'éclairage électrique. An improved fumigating composition. April 4.

8236. C. H. Higbee. An improved composition or material for destroying insects. Complete Specification. April 18.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Foods.

1895.

7508. W. Fraser. New food preparations, liquid and solid, for animal food. April 15.

1896.

3090. C. Kellner. Improvements in the reduction of organic compounds. March 25.

3103. A. J. Boulton.—From W. Meadows. An improved food and processes of preparing the same. April 8.

B.—Sanitation.

1895.

5834. G. Mugna. Improvements in or relating to the purification of smoke and recovery of soot from the products of furnaces. March 25.

10,891. C. A. Burghardt. Production of compositions adapted to be used in the treatment of sewage and other foul waters. April 8.

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

5987. S. W. Wilkinson and the Grove Company, Limited. Improvements relating to the treatment of articles of cellulose or cellulose compounds. March 17.

6014. J. Shaw. Improvements in heating engines or machines employed in the treatment of paper pulp. March 18.

6289. M. E. Asselot. Improvements in or relating to the manufacture of celluloid. March 23.

6836. S. W. Wilkinson. The manufacture of an improved substitute for ivory, celluloid, and the like. March 28.

7234. The British Xylonite Company, Limited, and S. W. Brooke. Improvements in the manufacture of xylonite, celluloid, and similar compounds of nitro-cellulose. April 2.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

2709. R. Aitken. Treatment of paper. April 15.

10,716. F. Stehle. Process for bleaching paper pulp. April 1.

12,461. L. de Naeyer. Apparatus for treating paper pulp. April 22.

24,272. A. Duffek and A. Merrel. Manufacture or preparation of cellulose suitable as a raw material for paper. March 25.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

6108. F. Sykes.—From R. Hirsch. A process for purifying saccharine. March 19.

6157. F. Brunjes. An improved process for the separation of silicic acid from argillaceous substances. Complete Specification. March 19.

6858. C. D. Abel.—From E. Bronnert and T. Schlumberger. Manufacture of solutions of tetranitro-cellulose (collodion pyroxyline). March 28.

6929. S. Frankel. A new pharmaceutical product and a process of obtaining the same. March 30.

7298. G. Dallmann. Process for making a preparation of iron applicable as medicament. April 4.

7692. O. Pren. Improvements in the manufacture of vanilline. Complete Specification. April 11.

7712. A. Classen. Production of formaldehyde compounds of the albumen and protein bodies. April 11.

7898. H. H. Lake.—From L. von Lorey, *z.* An improved process for raising permanent pure cultivations of lactic acid bacteria. April 14.

8154. J. C. Mewburn.—From The Chemische Fab. von Heyden, Gesellschaft mit beschränkter Haftung. A new product, being pyrocatechin-anhydro-mono-acetic acid, and a process or processes of manufacturing the same. Complete Specification. April 17.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6596. M. Otto and A. Verley. Manufacture of perfumes. April 1.

10,946. H. H. Lake.—From The Fabriques de Produits Chimiques de Thann et de Mulhouse. Manufacture of artificial musk. March 25.

11,287. O. Imray.—From Goerlich and Wichmann and Co. Manufacture of rhodan of sulphocyanide salts from nitrates, bisulphide of carbon, and sulphuretted hydrogen. April 1.

1896.

5672. E. Langheld. Ozone compounds for medicinal purposes. April 22.

XXI.—PHOTOGRAPHY.

APPLICATION.

6651. P. E. Schoenfelder and E. Kehle. Improvements in chemical compositions to be used for preparing the surface of suitable material for photographic prints. Complete Specification. March 26.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

5815. G. Craig. Improvements in the manufacture of nitrate of ammonium and in the apparatus therefor. March 16.

6052. G. Schwiening. Manufacture of igniting compound for matches. March 18.

6420. L. Waydelin. Improvements in or relating to detonating- or fog-signals for use on railways. Complete Specification. March 23.

6431. A. V. Newton.—From A. Nobel. Improvements in explosive compounds. March 23.

6555. R. Pierre and W. Pottgiesser. Improvements in the manufacture of safety explosives. Complete Specification. March 25.

6775. G. D. Day. Improvements in wax and other matches. March 27.

6937. W. Greaves and E. M. Hann. Improvements in or relating to explosives. March 30.

7612. E. Davies and H. M. H. Goodfellow. Improvements connected with explosive and non-explosive projectiles, and in an explosive compound to be used with explosive projectiles. April 10.

7711. M. Wagner. Improved manufacture of fuses or match-cords. Complete Specification. April 11.

7744. W. J. Clapp and F. P. Robjert. Improvements in the manufacture in match-boxes and matches. April 13.

8022. W. B. Ballantine, jun. Improvements in and connected with the fuses or projectiles. April 16.

8075. M. I. E. Morris. Improvements in explosives. April 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

9798. H. V. Keeson. Improvements in fuses for projectiles. April 22.

1896.

4714. M. Bals. Process for rendering amorphous phosphorus applicable as substitute for the yellow phosphorus for matches, primings, and the like. April 15.

PATENTS UNCLASSIFIABLE.

APPLICATION.

7793. C. Stahlshmidt. Improvements in or relating to the manufacture of a new product from sugar, brown iron ore, and chloride of sodium. Complete Specification. April 13.

COMPLETE SPECIFICATION ACCEPTED.

1896.

2090. G. L. A. Kuhlmann and J. Baier. A new and improved manufacture of a material suitable as a substitute for whalebone. April 22.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 5.—VOL. XV.]

MAY 30, 1896.

[Non-Members 30/- per annum; Members
21/- per Set of extra or back numbers;
Single Copies (Members only) 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
Dr. W. H. Perkin, F.R.S.	1884—1885.
E. K. Muspratt.	1885—1886.
David Howard.	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook.	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S.	1892—1893.
E. C. C. Stanford.	1893—1894.
Dr. T. E. Thorpe, LL.D., F.R.S.	1894—1895.

COUNCIL FOR YEAR ENDING JULY, 1896.

President: Thos. Tyrer.

Vice-Presidents:

<i>Sir F. A. Abel, Bart., F.R.S.</i>	T. Fairley.
<i>Horace T. Brown, F.R.S.</i>	Boverton Redwood.
<i>John Calderwood.</i>	Sir H. E. Roscoe, M.P., F.R.S.
<i>Chas. Dreyfus.</i>	E. C. C. Stanford.
<i>Dr. A. Dupré, F.R.S.</i>	Dr. T. E. Thorpe, LL.D., F.R.S.
<i>Sir John Evans, K.C.B., F.R.S.</i>	Prof. W. A. Tilden, F.R.S.

Ordinary Members of Council:

J. S. MacArthur.	C. C. Hutchinson.
C. A. Fawcitt.	Ivan Levinstein.
R. Le Neve Foster.	Sir Robt. Pullar.
W. Douglas Herman.	G. N. Stoker.
David Howard.	Wm. Thorp, B.Sc.
<i>Prof. A. K. Huntington.</i>	<i>Frank Wilson.</i>

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members whose names are placed in italics in the list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. Edward Schunck, F.R.S., has been nominated to the office of President; and Mr. Thomas Tyrer has been nominated Vice-President under Rule 11.

Prof. A. K. Huntington, Mr. A. H. Mason, and Mr. G. N. Stoker have been nominated Vice-Presidents under Rule 8; and the Treasurer and Foreign Secretary have been nominated for re-election to their respective offices.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18:—"No such nomination shall be valid unless it be signed by at least ten Members of the Society who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in London on the 15th, 16th, and 17th July next. The programme, with application form for tickets, will be found in this number of the Journal. Tickets of Membership will be issued in time for the meeting, and will form, as heretofore, vouchers for visits to works and excursions.

COLLECTIVE INDEX.

A collective index, embracing the whole Journal from the Proceedings of the First Annual General Meeting, 1881, to the close of 1895, is now in preparation, and will be ready in the current year. It will contain both a subject-matter and authors' names portion and will be a volume of about 500 pages, uniform in size with the Journal.

The prices will be as follows:—

To Members (see Rules 25 and 27) who make application with remittance, not later than June 30, 1896.....	Each copy	5s.
To Members (see Rules 25 and 27) who make later application; Libraries, Corporations, and Exchanges on the Society's List, and Past Members (see Rule 30)	Each copy	10s.
To Subscribers	"	12s. 6d.
To others.....	"	15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. EYRE and SPOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

MEMORIAL TO THE LATE PROF. HUXLEY, F.R.S.

This Memorial will take the form of a statue to be placed in the Museum of Natural History, and a medal in connection with the Royal College of Science, while the surplus will be devoted to the furtherance of biological science. Donations towards the fund should be sent to Mr. G. B. Howes, Hon. Sec. Huxley Memorial Committee, Royal College of Science, South Kensington, S.W.

MEMORIAL TO THE LATE PROF. PASTEUR.

At a meeting of the Provisional Committee of the British Section of the Pasteur International Memorial, held on March 21st last, Sir Joseph Lister in the chair, it was unanimously resolved, "That application be made for subscriptions towards the erection of a monument to Pasteur in Paris from persons in the United Kingdom, India, and the Colonies, interested in science and the various industries which have been benefited by Pasteur's labours." An Executive Committee was formed consisting of Sir Joseph Lister, Sir John Evans, Sir Henry Roscoe, Dr. Thorne Thorne, and Prof. Percy Frankland (Hon. Sec.). Subscriptions may be sent to Sir John Evans, who will act as Hon. Treasurer, at the Royal Society, Burlington House, W.

ADDRESS TO PROF. CANIZZARO.

At a meeting of Council held on March 23rd it was unanimously resolved to present an address of congratulation to Prof. Canizzaro on the attainment of his seventieth year of age, which occurs on July 12th next. The drafting of the address was placed in the hands of the Hon. Foreign Secretary of the Society.

INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

This Congress will be opened in Paris, possibly at the Hotel "des Agriculteurs de France," on Monday, July 27th next, and will continue for about ten days. All enquiries and adhesions should be addressed to the General Secretary of the Conference, 156, Bd. Magenta, Paris.

LIST OF MEMBERS ELECTED 22nd MAY 1896.

- Brooke, C. B., jun., Colne House, Brantham, near Manningtree, Xylonite Manufacturer.
 Brooke, S. W., Colne House, Brantham, near Manningtree, Xylonite Manufacturer.
 Dee, H. E., Purley, Surrey, Secretary (Aspinall's Enamel Company).
 Eyson, G. A., Leagrave Road, Luton, Beds, Dyer.
 Goetz, Isidore, Château de Peyet, par Labastide-de-Sérou (Ariege), France, Manager of Mines.
 Hall, S. G., East London Soap Works, Bow, E., Soap Maker.
 Kuttroff, Adolf, 128, Duane Street, New York, U.S.A., Chemical Merchant.
 Lederle, Dr. E. J., Health Department, New York City, U.S.A., Chief Chemist.
 Marshall, Percy S., School House, Lockwood, Huddersfield, Assistant Chemist.
 Van Laer, Norbert, Black Eagle Brewery, Burton-on-Trent, Brewer's Chemist.
 Wachtel, Gregory, 21, Nadejinskaja, St. Petersburg, Russia, Chemical Engineer.
 Woodward, Jas., 144, Osborne Road, Forest Gate, Essex, Government Analyst.

CHANGES OF ADDRESS.

- Allred, C. H., 1/o Heavitree Road; 8, St. Margaret's Road, Plumstead Common, Kent.
 Barrie, D. McL., 1/o Johannesburg; retain Journals until further notice.
 Bateson, P., 1/o Wavertree, Cuckoo Lane, Gateacre, near Liverpool.
 Beanes, E.; Journals to Moatlands, Paddock Wood, Kent.
 Bischoff, Dr. E.; Journals to 227, East 19th Street, New York, U.S.A.
 Brunner, J. F. L., 1/o Northwich; 23, Wetherby Gardens, London, S.W.
 Burdakin, G.; Journals to Park Villa, Prescott Road, St. Helens.
 Carmody, Prof. P.; Annual Meeting Notices to 225, Friern Road, Dulwich, S.E.; Journals as before.
 Chadwick, Walter N., 1/o Bayonne; c/o Pennsylvania Salt Manufacturing Company, Natrona, Pa., U.S.A.
 Constable, W. H., 1/o Widnes; The Birches, Seabank Road, Liscard, Cheshire.
 Crompton, Percy R., 1/o Dearden's House; Elton Paper Mills, near Bury, Lancashire.
 Doidge, H., 1/o Town Hill; 112, Loop Street, Pietermaritzburg, Natal.
 Dreaper, W. P., 1/o Prince's Road; 80, Middle Market Road, Great Yarmouth.
 Flammer, E., 1/o Manchester; Heilbrunn a/N., Würtemberg.
 Haga, T., 1/o Tokyo; Schlüterstrasse 72", Charlottenburg, Berlin.
 Hamburger, Aron, 1/o North Wales; 103, North Front Street, Philadelphia, Pa., U.S.A.
 Hewitt, J. Theo.; Journals to 11, Venuer Road, Sydenham, S.E.
 Hill, Jas. Kay, 1/o Irvine; 13, Osborne Place, Copland Road, Govan, near Glasgow.

The following have been elected to fill the vacancies, and will take office in July next:—Chairman: R. Messel. Committee: W. J. Dibdin, R. J. Friswell, D. Howard, B. E. R. Newlands, B. Redwood, and T. Tyrer.

SESSION 1895-96.

June 1st:—

Mr. W. Gowland. "Japanese Metallurgy." Part I.

Mr. S. Cowper-Coles. "The Electro-deposition of Zinc."

Meeting held Monday, May 4th, 1896.

DR. R. MESSEL IN THE CHAIR.

ARTIFICIAL SILK (LUSTRO-CELLULOSE).

BY C. F. CROSS AND E. J. ELVAN.

The production of a lustrous thread of cellulose in continuous length, by the process of drawing or "spinning" is at this date an accomplished fact, ranking not merely as a technical curiosity, but as a commercial development. The term "artificial silk" by which this product is designated is in some sense an unfortunate one, involving as it does a confusion of the incidental aspects of structure or form with the essential properties of matter or substance. Given a solid homogeneous cylinder of cellulose, there were *a priori* grounds for expecting the substance in this form to show high lustre. Now that the product is before us, and we have to inform ourselves about it as technologists and not as, let us say, journalists, we may very well begin our enquiry by eliminating the term "silk" as involving exclusive title to the properties of high lustre and elasticity. Those who are familiar with vegetable fibres and fibrous products are well aware that the forms of natural cellulose comprise a wide range of variations of these characteristic properties, and that these variations closely correspond with difference of minute structure, being dependent in much lesser degree upon variations of chemical composition.

A superficial comparison of cotton, flax, and the cellulose well illustrates this point. These products are indistinguishable chemically, *i.e.*, may be considered as one and the same substance; in appearance and generally in their characteristics, on the other hand, they are strongly differentiated. Microscopic examination reveals the effective causes of these differences. The cotton fibre is a flattened or collapsed tube with thin membranous side wall; the bast fibres on the other hand, are polygonal or cylindrical in outline, with side walls relatively thick in proportion to the central canal; the side walls, moreover, tend to break up when disintegrated into fibrillae parallel to the axis. These structural features impart a decided capacity for reflecting light, whereas the structure of cotton contributes to the breaking or scattering of light, *i.e.*, to inferior lustre. These points have been systematically dealt with by Vétillard in his "Études sur les Fibres Végétales Textiles" and by O. Witt in his "Chem. Techn. d. Gespinnstfaser" and elsewhere.

Witt has discussed these points by the very suggestive method of what we may term "diagrams in substance." He takes glass as a typical colloid and draws it under heat into forms corresponding roughly with the textile fibres. Thus a solid rod drawn or spun into a solid thread is a crude diagram of silk; a thick walled glass tube drawn into continuous thread roughly represents flax; a thin walled tube of elliptical section would similarly furnish a diagram of cotton, save that the membranous character of the side walls could not be reproduced. It is obvious, however, that in these three forms the glass presents very distinct grades of lustre. The parallel need not be pursued into minute detail. We may revert for further illustration of our text to certain vegetable fibres of less common occurrence in which the approximation in external features to silk is very much closer. Thus the bast fibres of *Calotropis*, and of *Marsdenia Tenacissima*, yield celluloses of quite remarkable lustre; and the seed hair of the *Eriodendron Anfractuosum* is well known as silk-cotton, on account of its resemblance to silk.

By certain chemical treatments also the lustre of the vegetable fibres is considerably increased. Thus on nitrating the *calotropis* fibre, a product is obtained of remarkable brilliancy. The jute fibre by a treatment of a very different kind, *viz.*, immersion in strong solution of caustic soda (12–20 per cent. NaOH) and washing off, is rendered much more silky and lustrous. These effects are due to changes first in the fibre bundle, which is broken up into smaller units, of more regular outline and free from cellular parenchyma; secondly, in the individual bast fibres which present a considerably thickened cell wall, the central

causal being almost obliterated, and a smooth external contour. It is clear, therefore, that vegetable structures composed of nitrogen-free colloids are found in forms closely approximating to silk in respect of its especial characteristic of lustre. In regard to such properties as elasticity and tensile strength, these no doubt depend directly upon substance or molecular constitution and are modified in a secondary degree only by the particular features of external form. Into such questions we make no pretension to enter.

The particular features of interest of this addition to the textile fibres of a lustrous cellulose are: (1) the incidents of its conversion into a soluble form and then into a solution of sufficient concentration to fit the mechanical requirements of continuous solidification to a thread, and (2) the properties of cellulose which enable it to withstand a cycle of severe chemical treatments to reappear in its final form in a condition but little removed from that of the original substance.

We find it necessary to emphasise the fact that this product in its final state, *i.e.*, as put upon the market, is a cellulose, a structureless form of the parent substance, by reason of the appearance quite recently and in this Journal (1895, 720) of the statement that it is an explosive or highly inflammable material. We may briefly recall the steps of the process: (1) the nitration of the cotton, and its solution in ether-alcohol; (2) the drawing of the viscous solution of cellulose nitrate through fine orifices of glass and its precipitation by water (Lehner) or solidification by evaporation of the solvent (Chardonnet), continuously to a fine thread. These threads are thrown or twisted together to form the compound thread or textile yarn; (3) the nitrate yarn thus prepared is next denitrated, *i.e.*, the nitric ester is resolved, the cellulose thread retaining its form and lustre and constituting the artificial silk, or to coin a more suitable term, lustrous-cellulose of commerce.

These processes, considered chemically, are extremely simple no doubt, and in themselves contain no essential elements of novelty. The merits of the achievement of the inventors who have perfected the production of this textile are to be found in other directions. In each stage of the process, formidable difficulties have had to be met and overcome. There have been not merely the difficulties involved in an excessively fine adjustment of chemical and physical properties and conditions both in the material operated upon, and the necessary details of the operations, but there have been the difficulties of ways and means, which from the special character of the undertaking must have been exceptional, and the strain upon the personal qualities of energy and perseverance which cannot have been less considerable. These should not be left out of consideration in view of the apparent and indeed actual simplicity of the perfected scheme.

We do not propose to consider the working details of the processes; we refer below to the pages of the Society's Journal on which abstracts of the patents of Chardonnet and Lehner appear.*

It is the final product to which we wish to direct special attention, and for which we wish to secure recognition as a cellulose.

The investigations we have made of this product were directed to the answering of the following questions upon the points more or less in doubt:—

1. Is the denitration of the nitrate complete in regard to the removal of the nitric groups (NO_2)?
2. Does the cellulose residue in denitration revert to the normal molecular condition of the original?
3. Is the cycle of operations accompanied by hydration changes, or such movements of oxygen as might give rise to an oxy-cellulose of the same empirical formula as cellulose?

(1.) The first question was at once answered in the affirmative by an estimation of nitrogen. The lustrous-cellulose was found to contain only 0.19 per cent. N.

(2.) The elementary composition was determined by combustion, and the following numbers obtained:—

C	43.77
H	6.40

These are in accordance with sufficient approximation with the formula of a normal cellulose. Question 2 is therefore answered satisfactorily and in the affirmative.

(3.) For the presence of oxy-cellulose compounds we examined the product: (a) by the furfural test; (b) by the cupric reduction test. Both gave negative results. On boiling with HCl Aq (sp. gr. 1.06) traces only of furfural were formed; and on boiling with dilute solution of sodium hydrate, with addition of Fehling's solution, no reduction took place. The latter result was confirmed by a quantitative estimation of the loss of weight on long boiling in a solution of sodium hydrate of 1 per cent. NaOH . The loss sustained was 9.14 per cent. This indicates a much higher resistance to alkaline hydrolysis than might have been predicted. As the constituents hydrolysed and dissolved are without reducing action on cupric oxide, they retain the cellulosic character, and represent therefore soluble cellulose hydrates.

The answer to the question propounded is therefore that no oxy-cellulose results from the cycle of operations, and that the permanent hydration changes which take place are of minor importance.

Hence our conclusion that the new "artificial silk," or, as we prefer to call it, lustrous-cellulose, may be considered as substantially a normal cellulose.

In regard to the properties of this textile in other respects, we find that the "hygroscopic moisture" is, as might be expected, much higher than in the "natural celluloses," *viz.*, 10–12 per cent. According to the official comparative tests the tensile strength of the yarn is inferior to that of silk in the proportion of 70 to 100, and its elasticity is in somewhat lower ratio. In regard to its dyeing capabilities, we may say generally they are considerable. A comparative quantitative study of the structureless celluloses with the ordinary fibrous celluloses in regard to absorption of colouring matters of known constitution will be made in due course, and the results cannot fail to throw important light on the "theory of dyeing." We do not propose to anticipate these results by any general statement.

It will be sufficiently evident from the samples displayed that the range of colour effects obtainable is as wide as it is brilliant.

Nor do we propose to say anything as to the commercial prospects of the new industry. We have merely to note that the lustrous-cellulose finds a ready sale at high prices; and the margin between these prices and the cost of production is stated to be large.

Our object in this communication is rather to call attention to the scientific and purely chemical features of a new and in many respects unexpected development of the rapidly widening technology of cellulose.

DISCUSSION.

Dr. S. RIDEAL said that the Society was indebted to Mr. Bevan for bringing the manufacture of artificial silk before them. Some years ago he had had occasion to examine different patents relative to the manufacture of artificial silk, and he came to the conclusion that they were all very similar, and that the chief difficulty was unsatisfactory denitration. Since that time considerable progress had been made in that direction, and the experiments shown by Mr. Bevan had demonstrated that it was quite possible to remove sufficient of the nitrogen to render the product inexplosive. That being the case, it opened out the possibility that treatment with ammonium sulphite would prove equally beneficial in the manufacture of cellaloid. As that material was being largely used for electrical insulating purposes, it necessarily required to be of an inexplosive and unflammable character.

A MEMBER asked what official tests of the tensile strength of silk were referred to. As the members present knew, there were no official tests in England. Probably the author alluded to tests made in Germany or Switzerland.

* Chardonnet:—This Journal, 1887, 139; 1889, 474; 1891, 559 and 566; 1892, 939; 1895, 33.

Lehner:—This Journal, 1892, 680; 1893, 1024; 1894, 1192.

Mr. CROWDER wished to know whether these nitrogenous substances were dyed with or without a mordant. The nitrogen having been almost entirely removed, was the cellulose dyed as a silk, a nitrogenous substance, or as cotton, a non-nitrogenous substance?

Mr. WATSON SMITH asked whether it was the practice to dye the nitrocellulose first and then to denitrate it.

Dr. S. RIDEAL wished to know the actual cost of denitration. He understood that sulphite of ammonium was the reagent employed, and he thought it would be interesting to know in what form the nitrate was eliminated when the sulphite of ammonium was added.

Mr. BEVAN said, in reply, that when he referred to official tests, he meant tests made by officials competent to do so. He did not wish to mislead the members by using that term; there was very little doubt, however, that the tensile strengths were what he stated. With regard to the process of denitration it was a very well-known one, although he could not tell in what form the nitrate was eliminated. The denitration process took place before the dyeing operation; the substance was reconverted into cellulose and then dyed. With regard to Mr. Crowder's observations as to whether the cellulose was dyed as a cotton or as a silk, he might say that the cellulose always behaved precisely as an ordinary cotton and required a mordant to enable it to take a dye properly.

DR. G. SCHACK-SOMMER IN THE CHAIR.

THE ACTION OF CARBON-MONOXIDE AND COAL-DUST IN PROMOTING COLLIERY EXPLOSIONS.

BY W. J. ORSMAN, F.I.C.

PROF. H. B. DIXON in his classical researches on the combustion of carbon has shown that the tendency of hydrocarbons, and probably carbon, when burnt in air, is to first form carbon-monoxide, and that this gas, if excess of oxygen be present, further burns to form carbon dioxide. Professor Dixon has also shown that carbon monoxide forms explosive mixtures with air and oxygen, the velocity of the explosive wave formed reaching a maximum in the presence of about 5 per cent. of water vapour. The heat of combustion of one gramme of carbon burning to form carbon dioxide is 8,080 units, and in burning to form the monoxide is only 2,473 units; the difference, therefore, of 5,607 will show the number of units of heat evolved in the burning of the monoxide to the dioxide.

Prof. Vivian Lewes has demonstrated the fact that coal-dust will readily burn in mixtures of air and carbon-monoxide, and has shown that a small proportion of carbon-monoxide present in a dusty atmosphere will constitute a most explosive mixture.

It is well known that explosions have occurred in flour-mills and other places in which a dusty atmosphere has been present, but these are of very rare occurrence, and it is a matter of extreme difficulty to cause an ignition of dust by means of a naked flame. If such ignitions were easy, we should have constant explosions in the dusty atmospheres in coal-mines where naked lights are used. We therefore have to look for some further explanation for the disastrous explosions which sometimes occur in mines, in which, as far as could be proved, no inflammable gas was found either before or after the explosion.

Until very lately explosions in mines were always attributed to the presence of firedamp, and for this reason the adoption of safety lamps has been made compulsory in gassy mines. To prevent the accumulation of gas in the workings increased ventilation has been resorted to, and the conditions of safety have materially advanced during the last few years.

In consequence of explosions occurring where the method of working and general circumstances precluded the possibility of gas being present, it was suggested that coal-dust itself might constitute an explosive agent. On investigation it was shown by Mr. Henry Hall, Her Majesty's Inspector of Mines, and Mr. W. Galloway that this was the case, and that an explosion could be initiated by a blown-out shot and carried on in a dusty atmosphere without any firedamp being present.

With regard to the explosions caused by coal-dust and air alone, I would refer you to the second report of the Royal Commission on explosions from coal-dust in mines, published in 1894.

Of great interest, also, are the experiments made by Mr. Henry Hall at the latter end of 1892 and the early part of 1893, and reported upon by him to the Secretary of State on January 23rd 1893, in which he shows by conclusive experiments that dry coal-dust, under conditions frequently present in coal mines, and in the entire absence of firedamp, may be inflamed by a blown-out gunpowder shot, and cause a disastrous colliery explosion.

The above experiments may be briefly mentioned here, as these were conducted on a large scale and under conditions most nearly representing actual mining operations.

The experiments were conducted in a disused shaft at White Moss Colliery, Skelmersdale. The shaft was 50 yards deep and 7 ft. in diameter, and struts of timber were fixed from top to bottom to represent the timbering on an underground roadway. The ventilation was effected by means of a fan at the surface forcing fresh air through 10-in. iron pipes to the bottom of the shaft.

In order to fire the shots, a wrought-iron cannon of considerable strength was used, placed in an upright position. When the cannon was charged, stemmed and ready for firing, coal-dust was sprinkled down the shaft and partially allowed to settle; in this way about 80 lbs. of dust would be available for explosion purposes.

The phenomena presented by these experiments as they progressed, and a careful examination of the detailed results, were productive of the following conclusions, which may be best stated in Mr. Hall's own words:—

1. That the flame from a blown-out gunpowder shot in the presence of dry coal-dust *always* ignites more or less of such dust, and so increases the burning and charring effects of the shot. This is proved by the fact that in almost every experiment which did not result in an actual explosion of dust there was nevertheless severe charring of the electric firing-cable for several yards up the shaft, whilst without dust and with a similar charge of explosive no such charring occurred.

2. That when a large flame (such as that of a blown-out gunpowder shot, or the flame from the ignition of a small quantity of firedamp) traverses an atmosphere containing a very moderate quantity of dry coal-dust, the dusty atmosphere will explode with great violence, and the explosion will continue on and pass through any length of such atmosphere, its violence and force increasing as it progresses. This is proved by the fact, that, in nearly every case, where the cannon was fired whilst there was dust suspended in the atmosphere of the shaft, a violent explosion followed, the force of which was evidently only,

beginning to be developed as it reached the top of the shaft and escaped, spending itself in the outside air, the flame in some cases attaining a height of 70 ft. over the top of the shaft.

3. That coal-dust from several seams in different districts, notably those from Glamorgin, Monmouth, Durham, Lancashire, Yorkshire, and Scotland, are almost as sensitive to explosion as gunpowder.

4. That coal-dust is, as a rule, more sensitive to explosion in proportion to its high quality and freedom from impurities.

5. That a ready supply of oxygen, such as is supplied by a brisk ventilation, has the effect of making coal-dust explosions more probable and more severe.

6. That certain "high explosives" are incapable of igniting or exploding coal-dust. In the experiments charges of roborite, and in two or three cases ammonite, were fired without effect, but as soon as gunpowder was introduced, its explosion was followed by violent dust explosions. The difference in the behaviour of gunpowder as compared with the high explosives was most impressive and convincing.

Having established the fact that coal dust could be easily ignited by a blown-out shot of gunpowder, it was of interest to ascertain the cause of such ignition, and from a number of experiments it is evident to my mind that the initial explosion is due to the presence of carbon-monoxide, produced by the explosion of gunpowder. Ordinary blasting powder varies greatly in composition, but all contain an excess of carbon, with the consequence that large volumes of carbon-monoxide are formed, in some instances as much as 32 per cent. of the total gases. This carbon monoxide comes together with the heated solid products of the combustion in contact with coal-dust, either previously in suspension or stirred up by the force of the explosion, the coal-dust ignites, and in burning produces the intermediate product carbon-monoxide, which, being driven rapidly ahead of the explosion and coming in contact with more dust and more air, produces a new explosive zone, and so traverses the whole of the dust-laden pit.

In order to get some idea of the condition of the air inside the pit whilst an explosion was in progress, I arranged, at the time of Mr. Hall's experiments in 1892, a method of taking samples of the air. Two brass tubes, filled with water, were fastened to the rope that was used to lower the cannon, one 20 yards from the bottom, the other 40 yards from the bottom.

These tubes were so arranged and constructed that the explosion, as it passed the tubes, unsealed the outlet pipe and the escaping water allowed the ingress of a sample of air, which was trapped by a special arrangement and kept in the tube until the rope could be wound up. By this method it was intended that the sample of gas taken should represent the state of the air whilst the flame was passing, or directly afterwards. The lower tube, as the analysis will show, did partly collect the gas in the above condition. The tube at the top, however, commenced to act prematurely, and was probably started by the sound wave which preceded the explosion. This tube simply contained ordinary air.

The following is an analysis of the gases found in the lower tube:—

	Per Cent.
Oxygen.....	3.9
Nitrogen.....	75.9
Carbon-dioxide.....	12.1
Carbon-monoxide.....	8.1
	100.0

In order to test the action of the gases given off on the explosion of different explosives, small cartridges have been fired in a specially constructed steel bomb, and the gas produced mixed with air in a large cylinder. On sprinkling coal-dust in and applying a light, the dust ignited easily and burnt away fiercely. It will be seen, therefore, that the presence of carbon-monoxide in the air of a mine in small quantities is not only dangerous to health (1 per cent. being fatal), but also constitutes, when in the presence of coal-dust, a most explosive mixture, and it is only a matter of time when the use of gunpowder will be prohibited altogether in coal mines.

On examining the other explosives now coming into use, it is found that those which do not produce carbon-monoxide, or other inflammable gases, such as those of the Sprengel class, containing nitrate of ammonium, are very safe in dusty mines; whilst others, which produce inflammable gases, are as dangerous as gunpowder. In experimenting with the bomb, and on a larger scale with blown-out shots from a cannon, some very curious results have been obtained.

In order to render an explosive less liable to ignite fire-damp, it is necessary to lower the temperature of explosion, and in one class, of which the explosive carbonite is a member, this is accomplished by adding an excess of wood-meal. The composition may be taken as follows:—

Nitro-glycerine.....	25 parts.
Wood-meal.....	40 "
Potassium nitrate.....	34 "

The excess of wood-meal has a distinct effect in lowering the temperature, but it causes the production of 40 per cent. of inflammable gases. This explosive, when fired into an explosive mixture of fire-damp, is remarkably safe, and it is difficult to cause ignition. When, however, carbonite is fired into a mixture of air and coal-dust without fire-damp, it has been possible to get repeated and violent explosions.

If the carbonite be fired from a cannon into a gallery or chamber, and, after firing, dust be sprinkled in, and a light be placed near the mouth of the cannon, the gas catches fire, and we can produce a secondary explosion. We have here a curious instance of a mixture of dust and air being more explosive under certain circumstances than the most explosive mixture that can be got of coal-gas and air.

Many theories are held regarding the propagation of explosion in a dusty mine, the principal one being that the coal-dust, by the action of heat, becomes distilled, and yields the inflammable gases necessary to continue explosion. The production of these gases may undoubtedly have some effect, but I am firmly of opinion that the propagation is principally due to the continuous production of carbon-monoxide, which causes rapid combustion of dust and air as long as they are present. It is found that lampblack and other finely powdered forms of carbon burn in the presence of carbon-monoxide as easily as coal-dust.

Further, all coal dusts are sensitive, provided they are in a fine state of division and free from any large admixture of dirt. The reason why certain dusts have been stated to be safe, because they did not catch fire when experimentally tried, is due to the fact that they were contaminated with dirt (by reason of the traffic through the pit), and so yielded a large percentage of ash.

CHLORINE AS A DISINFECTANT.

BY G. C. CLAYTON, PH.D.

By the term "disinfection" we now understand the destruction of the germs which cause disease, and the term "disinfectant" should therefore not be applied to antiseptics, which simply retard their growth, or to deodorants, which destroy, or only mask, the odours caused by them.

It has been proved that light and air, if given sufficient time, will destroy most bacilli, still the fact remains that the virus of scarlet fever and of other diseases has been known to retain its vitality for years, and small-pox has been carried long distances by air-currents, landing in an inconveniently lively condition. Unfortunately, owing to the crowded state of the world, men cannot nowadays allow a sufficient space of air and sunshine between themselves and their neighbours to run even a moderate chance of safety, and are obliged to fall back on artificial disinfection. There are two methods of disinfection open to us—by heat and by chemical means.

Heat is certainly the most satisfactory, but unfortunately it cannot be universally applied, and so one is forced in many cases to make use of chemical reagents.

Chlorine, either in a gaseous form or in combination, has long been used as a disinfectant, and used with undoubted success. My object in reading this paper has been first to record the results of some experiments made on this subject by Professor Boyce, of University College, Liver-

pool, and also by myself, and, further, to collect for general use the results of the chief investigations, which have been done on the disinfecting action of chlorine.

I will treat my subject under three headings—

1. Chlorine as a gas or as chlorine water.
2. Chlorine as bleaching powder.
3. Chlorine as sodium hypochlorite.

Chlorine.—Chlorine acts as an active germicide on account of its affinity for hydrogen, and the consequent release of nascent oxygen when it comes in contact with micro-organisms in a moist condition.

Fischer and Proskauer showed that dried anthrax spores were unacted on, even when exposed to a 44·7 per cent. dry chlorine, whereas, when moistened, 4 per cent. was effective. With an exposure of 3 hours 1 per cent. was sufficient. This proves that chlorine does not act as a poison, but as an oxidising agent.

In the case of anthrax bacilli, not spores, 0·04 per cent. chlorine was fatal in 24 hours.

Koch found that anthrax failed to grow after 24 hours exposure to 2 per cent. chlorine water.

In a paper entitled "A report on Chlorine, Bromine, Iodine, and Sulphurous Acid," by Dr. Cash, F.R.S. (16th Report, Local Govt. Board, 1886-87), I find the following:—

Two parts of anthrax blood are sterilised by 100 parts chlorine water containing 0·0034 per cent. chlorine in five minutes. Anything less than this gave variable results. Again, one part of strong anthrax spore broth was completely sterilised in 24 hours by 0·0355 grms. chlorine.

He found, as a result of a series of experiments, that it was safer to use a strong solution of chlorine for a short time than a weak solution for a long time.

Dr. Klein did some experiments on disinfection by means of gaseous chlorine. He selected swine fever, and found that a healthy animal could safely be placed in the same compartment with a diseased one for so long a time as six hours on five successive days, provided the compartment was fumigated with chlorine up to marked pungency twice within six hours.

Dr. Wynter Blyth, in a paper read before the Society of Medical Officers of Health, March 1885, said: "I consider that the best and most efficient way to disinfect a room after disease is to make it as much as possible like a hermetically sealed box, and in this box to evolve chlorine, 3 lb. of chloride of lime and 3 lb. of hydrochloric acid being used for every 1,000 cu. ft. of space."

German experiments, however, appear to indicate that the quantity of bleaching powder required for every 1,000 cu. ft. is more nearly 15 lb. than 3 lb.

Mr. James Hargreaves lately read a paper before the Liverpool Polytechnic Society dealing with this subject. His idea was the disinfection of sewers by means of chlorine, which he proposed to manufacture by the electrolysis of salt.

Of course the idea of treating, or attempting to treat, the entire sewage of a town by chemical disinfectants is opposed to the theory and practice of all modern sanitary engineers, and quite rightly. With proper arrangements and careful supervision the bulk of sewage can be treated perfectly safely and satisfactorily without disinfection. The use of disinfectants in the present day is to sterilise the sewage of hospitals for infectious diseases, of infected areas in the case of an epidemic, to kill the germs left after infectious diseases in the rooms of houses or hospitals, or likely to be

preserved on furniture or in clothes. Again, disinfectants are required in agricultural districts in cases of anthrax or swine fever.

Gaseous chlorine is not at present, so far as I know, on the English market, and when required for disinfecting purposes it has to be prepared in the way mentioned by Dr. Wynter Blyth.

Bleaching Powder.—Bleaching powder contains about 35 per cent. of available chlorine. The American Health Association, 1885, found that 0·25 per cent. chlorine as bleaching powder was an effective germicide in 1 or 2 minutes.

Bolton found that 1:2000 (available chlorine 0·0125) destroyed typhoid bacillus and cholera spir in 2 hours, while anthrax spores required a 1 per cent. solution (0·3 per cent. available chlorine).

Nissen gives the following:—

	Time.	Bleaching Powder.
	Mins.	Per Cent.
Typhoid and cholera.....	5	0·12
Anthrax bacillus.....	1	0·1
Staphylococcus pyogenes aureus.....	30	0·2
Anthrax spores.....	30	5·0
" ".....	70	1·0

Koch says that a 5 per cent. bleaching powder solution gave doubtful results, even after several days. From the fact that ordinary bleaching powder contains about 44 per cent. CaO, it is not a suitable disinfectant for sewers, nor, indeed, in any case where the material to be disinfected eventually comes into the sewers. This has undoubtedly been one of the factors which has told most largely against bleaching powder, and has prevented its more extended use.

Sodium Hypochlorite.—Sodium hypochlorite combines all the advantages of bleaching powder with fewer disadvantages.

It must not be kept on stock in very weak solutions, as in that case it is very unstable, as described by Sir Henry Roscoe and Mr. Lunt in a paper on "The Hermite Process" (this Journal, 1895, 224); but when the solution contains 10 per cent. available chlorine, or more, it retains its strength for a considerable time.

A sample of hypochlorite, 10·2 per cent. available chlorine by weight, when tested one month later contained 9·9 per cent., which gives a loss of only 2·9 per cent. in one month.

The following are some extracts from work done by Prof. Boyce on the germicidal properties of sodium hypochlorite.

The stock solution used was 10 per cent. available chlorine by volume.

The method adopted was as follows:—

By means of a sterilised pipette 5 c.c. of a known hypochlorite solution were added to 5 c.c. of an abundant broth cultivation in a sterilised flask. This was allowed to stand in contact for 2—2½ hours, with constant shaking to ensure complete admixture, and then sub-cultures were made in three broth-tubes by means of a platinum wire loop, taking every precaution against contamination. The three tubes were then incubated at 35° C., and examined on the next and following days.

The accompanying table shows the results:—

Time of Contact..	1% for 2½ Hrs.	1% for 20 Hrs.	1% for 2 Hrs.	1% for 2 Hrs.	2% for 2 Hrs.	3% for 2 Hrs.
Age of Sub-culture	24 Hrs.	24 Hrs.	24 Hrs. 48 Hrs.	24 Hrs. 48 Hrs.	24 Hrs. 48 Hrs.	No growth.
Bacillus coli.....	Good growth	Very slight growth	Growth Abundant growth.	V. s. g. G.	V. s. g. G.	No growth.
" typhosus	"	"	"	N. g. "	N. g. "	"
" cholerae.	Slight growth	"	No growth.	"	N. g. "	"
" anthracis	"	"	"	"	G. "	Grew ultimately.

This table shows that under a very severe test 3 per cent. solution (0.3 per cent. available chlorine) kills the above-named organisms, with the exception of anthrax when spore-bearing, under which circumstances anthrax is one of the most, if not the most, resistant of all bacilli.

Experiments with putrid egg and broth solution showed that the sterilisation was effected with 2 per cent. hypochlorite (0.2 per cent. available chlorine), while with 1 per cent. (0.1 per cent. available chlorine) all organisms present but the hay bacillus were killed.

A number of experiments were made with albumin as follows:—

1 c.c. pure white of egg was added to 5 c.c. broth culture, and then 5 c.c. hypochlorite solution. It was found that the

hypochlorite decomposed the white of egg without an appreciable retardation of its action.

This is an important consideration, as all sewage contains albumin.

As Prof. Boyce's investigation does not apply to the anthrax bacillus when spore-bearing, I undertook some experiments to find out what concentration and what length of time was required to destroy the organism under these circumstances with sodium hypochlorite. I followed the same method as that employed by Prof. Boyce, but made my sub-cultures after a contact of one, ten, and thirty minutes respectively, using as a stock solution an anthrax broth cultivation, which was incubated until the presence of spores was observed microscopically. My results are given in the adjoining table:—

Method of Experiment.	Percentage of Disinfectant present.	After 1 min.	After 10 mins.	After 30 mins.	—	Remarks.
1. 5 c.c. broth + 5 c.c. (10% av. cl. sol.)	50% stock sol., 5% av. cl.	0	0	0		Gelatine stab culture. Completely sterilised.
2. " " (5% av. cl. sol.)	25% " 2.5% av. cl.	+	+	0		Gelatine streak culture. No. 2 was retarded.
3. " " (2% av. cl. sol.)	10% " 1% av. cl.	+	0	0		Gelatine stab culture.
4. " " (2% av. cl. sol.)	10% " 1% av. cl.	+	+	+		Gelatine streak culture. No. 3 retarded, but not destroyed.
5. " " (1% av. cl. sol.)	5% " 0.5% av. cl.	+	+	+		Gelatine streak culture. Abundant growth.
6. " " " "	" " "	1 Hr. +	2 Hrs. +	3 Hrs. +	4½ Hrs. 0	No. 3 hindered, but not destroyed.

0 Sterilised.

+ Unsterilised.

No. 4, after 24 hours' contact a sub-culture showed a growth in three days, which proved to be anthrax; therefore hypochlorite of soda, 1 per cent. available chlorine, will not kill anthrax spores in 24 hours, but will only retard their growth.

To destroy the spores the solution must contain 2.5 per cent. available chlorine, and must act for 30 minutes. It is almost impossible to compare work done on this subject by one investigator with that done by another, as each man has his own particular methods, so that the figures given have very little relation to each other; also one cultivation differs materially from another in regard to its activity, depending on its attenuation, that is to say, the length of time it has been artificially cultivated since it last passed through a living body.

As far as one can judge from the results I have collected, it seems that chlorine acts equally energetically whether it be gaseous or in the form of bleaching powder or sodium hypochlorite. All three have a great advantage over corrosive sublimate, carbolic, and the numerous cresol disinfectants, in that chlorine dissolves albumen instead of precipitating it, thereby helping to disintegrate solid fecal matter, which is necessary before complete sterilisation is possible.

In cases where there is a large amount of albumen present an excess of the disinfectant is necessary, as a portion of the oxidising power is exhausted in the simple oxidation of organic matter before the bacteria themselves are acted on. This, of course, applies to all disinfectants which rely on oxidation. On the other hand, where phenol, &c. are used, the albumen is made insoluble, and bacteria imbedded in a casing of insoluble albumen never come in contact with the disinfectant, however large the quantity present may be, and these bacteria, when the conditions become more favourable, are a serious source of infection.

I found that a 1 per cent. available chlorine sodium hypochlorite solution dissolved white of egg readily with liberation of chlorine.

Comparison of sodium hypochlorite with other disinfectants gave the following:—

Sodium hypochlorite. { 2.5 per cent. available chlorine acted in ½ hour.
5.0 per cent. available chlorine acted in 1 minute.
5.0 per cent. phenol did not sterilise.
0.5 per cent. mercuric chloride acted in 1 minute.

Unfortunately, owing to its extremely poisonous nature and high price, corrosive sublimate is not generally applicable.

Amongst the many advantages possessed by sodium hypochlorite is the fact that it is miscible with water in any proportion, even in the presence of large quantities of salt, and as it readily gives off chlorine, colonies of bacteria which have been left on the walls of sewers above the present water level are destroyed, which would, of course, have escaped in the case of ordinary liquid disinfectants.

In conclusion I must express my thanks to Prof. Boyce for permission to make use of his results, and for help given me in my own work.

EXPORTS OF HEAVY CHEMICALS.

BY EUSTACE CAREY.

A SERIES of interesting and able articles under the title "Made in Germany" have been appearing recently in the *New Review*, the one in the May number being of especial interest to us. The writer shows how the chemical trade has grown in other parts of the world to a greater extent than in the United Kingdom, and he states why this has been so. But in speaking of "heavy chemicals" the author gives figures showing apparently a great decrease in business in 1895 as compared with 1873. The statement shows that in 1873 the exports of heavy chemicals were to the value of close upon 3,000,000*l.*, whereas in 1895 the exports were only some 1,560,000*l.*—a very considerable decrease. Quantities, however, are omitted, and it is satisfactory to know that the quantity exported has by no means diminished, but, on the contrary, has increased, as the following table shows:—

	Tons in 1873.		Tons in 1895.	
Soda ash.....	133,779	Total alkali at 100 per cent. = 103,910	179,576	Total alkali at 100 per cent. = 177,512
" crystals.....	45,458		27,472	
Bicarbonate.....	8,019		18,887	
Caustic soda.....	33,465		91,388	
Bleaching powder	30,843		69,624	

It must be remembered that 1873 was a year of exceptionally high prices and of high costs, whereas 1895 was perhaps the lowest on record.

MR. GEO. T. FRANCE IN THE CHAIR.

ON BLISTER STEEL AND SOME POINTS CONCERNING ITS FORMATION.

BY T. W. HOGG.

NOTWITHSTANDING the enormous and increasing quantities of steel now being made by other processes, the higher qualities of steel are still largely dependent upon the old cementation process for their production.

This process is so simple that it has offered little opportunity for alteration or improvement. It is conducted now in the same manner as it was when first introduced into this country, and practically nothing is known of its early history.

Simple as this process is, it has so many points of purely chemical and scientific interest that it has frequently been the subject of prolonged investigation, but it is questionable whether any more definite or important information has been added to our knowledge since Percy wrote his famous treatise on the metallurgy of iron and steel.

Briefly described, the process consists in imbedding bars of iron in charcoal, contained in a suitable rectangular chest. This is then closed effectively to prevent the entrance of air, the temperature is gradually increased until it is considerably above a red heat, and, after several days of this treatment, the iron becomes impregnated with a sufficient quantity of carbon to convert it into steel.

It has occurred to me that a short paper upon this subject would be of some interest to the members of this Section, more especially when it is remembered that steel was made in this locality by this process probably even before it reached Sheffield, and at the present time I believe that the only makers of blister steel left in this district are Messrs. John Spencer and Sons, of Newburn.

An important noticeable peculiarity of the bars of iron after they have been converted into steel by this cementation process, is that they are covered with numerous blisters of varying size, sometimes even a foot in length, but generally they only vary between a quarter of an inch to two inches across.

Although there has always been a certain amount of doubt as to the origin of these blisters, the real cause of them seems to have been known to earlier observers than Percy, who ascribed their production to the presence of intermixed slag or cinder. The gradual action of carbon on steel at a high temperature upon the interposed silicate of protoxide of iron reduces the protoxide of iron to the metallic state with the liberation of carbonic acid, which causes the hot softened metal to expand in the form of a blister. It is a fact that previous fusion of the iron, so as to free it from all intermixed slag, completely prevents the formation of these blisters (Percy, *Journal of Steel Inst.* 1878). I am not aware, however, that anyone

has called attention to the fact that careful inspection of the interior of the blisters under a low degree of magnification seldom fails to reveal the presence of globules of slag or glassy material often in very large numbers. The globules which occur most frequently are very small, perfectly transparent, and colourless. As a rule, the brilliant, metallic, highly-illuminated surface of the interior of the blister is so dazzling that these globules easily escape notice, but they are always present in more or less abundance, and are doubtless due to the metallic constituent of the slag being gradually reduced and deposited. Occasionally there are present brownish, transparent globules, some opalescent with a greenish tinge, and, more rarely, others perfectly black and opaque, possibly these latter are the initial condition, and the colourless globules, the final condition of the interposed slag.

Many years ago I cut out several of these blisters and determined the intermixed slag, and also the silicon present in combination with the iron.

The following table contains some of the results:—

BLISTERS FROM DIFFERENT GRADES OF CEMENTATION STEEL.

Carbon	0.60	0.70	0.95	1.30
Interposed slag .	0.20	0.16	0.19	0.095
Silicon	0.015	0.005	Traces	Traces

In a paper read before the British Association in 1879, Mr. H. S. Bell described some experiments made to ascertain the proportion of silicon present in the blistered and unblistered portions of the bar, and he concluded that his results showed a marked increase in the silicon wherever the blisters occurred. This would be an important fact if true, but I feel pretty certain that this observer has fallen into the error of ascribing the silica obtained in the ordinary method of analysis to silicon, whereas it is in all probability mostly due to the decomposition of the intermixed slag existing naturally in the iron. The intermixed slag of course will be most abundant at the blistered portions of the bar.

In connection with these blisters I have much pleasure in showing you a curious and extremely rare substance which I have only met with upon two occasions. It completely filled the blisters and in appearance strongly resembles a metallic growth. It is a mass of irregular metallic filaments of the same composition as the surface of the bar underneath the skin, excepting that it contains an unusual proportion of interposed slag. I have not determined the exact quantity of this slag, but different portions of the substance have yielded impure silica to the extent of 2.90 per cent., 2.08 per cent., and 1.85 per cent., respectively. It would appear, therefore, that this slag is irregularly distributed throughout the mass.

It is probable that during the early stage in the formation of a blister there will be present numerous metallic threads of steel which have been gradually drawn out between those portions of the metal in perfect contact. The internal appearance of many blisters is strongly suggestive of this. After a time these threads will break and leave the cavity with an exceedingly rough and irregular surface. In what manner the curious spongy-looking mass of steel which I show you is formed I have no opinion to offer. It must be a very unusual occurrence, perhaps it is actually a metallic growth similar to those so well known in the cases of gold, silver, and copper. It contains 1.06 per cent. of carbon.

Coming now to the interesting questions with regard to the method by which the bar of iron becomes gradually impregnated with carbon. The various speculations upon this subject have been so well treated by Percy, that all as his book is, our increase of knowledge upon the properties of iron and carbon has been so slight and uncertain, it may still be advantageously referred to for the consideration of many of the questions involved.

The only attractive addition to our theories concerning the impregnation of the iron with carbon is the diffusion theory of Marsden (*Journal of the Iron and Steel Inst.*, 1881, I., p. 233). This theory, however, does not differ from Percy's otherwise than by concluding that the carbon

really permeates the porous mass of iron and does not combine with it, but remains existing as an extremely finely divided amorphous carbon. No other evidence for this is offered than the fact that carbon can be extracted from, as well as introduced into solid iron by a process of cementation, and that porcelain embedded in finely divided carbon gradually becomes permeated throughout. There is plenty of evidence, taken altogether, showing that it is pretty certain that the carbon in Blister steel is in a state of combination with the iron. The fact, that in all grades of Blister steel, even in the hardest, the carbon is in a condition which readily combines with hydrogen and is evolved as a hydrocarbon on treatment with hot dilute hydrochloric or sulphuric acid; also that it forms a compound on treatment with nitric acid easily soluble in this acid, would seem to indicate the absence of amorphous carbon to any considerable extent. It is not improbable that the small proportion of amorphous carbon sometimes present, is in fact really due to the decomposition during slow cooling of the normal carbide of iron diffused throughout the mass.

The following experiments give a little further information with regard to the actual distribution of carbon in different parts of the bar:—

Portions from each of two cemented bars of different degrees of hardness were taken. These bars were fresh from the furnace and had not been long exposed to the atmosphere. They were well scrubbed with fine sand and water with a hard brush, so as to perfectly remove all loosely adherent matter. These bars were then carefully planed so as to take off as little from the surface as possible. This first layer or skin was kept by itself. Another small thickness was planed off, and this operation continued until the centre of the bar was reached.

The carbon was then ascertained by colour-test in each layer, and the results obtained are given in the following table:—

CARBON BY COLOUR-TEST IN DIFFERENT LAYERS FROM BLISTER STEEL.

	A.	B.
	Per Cent.	Per Cent.
layer (skin)	0.09	0.12
2nd "	0.34	0.34
3rd "	0.81	0.47
4th "	0.68	0.40
5th "	0.62	0.35
6th "	0.57	0.26
7th " (centre)	0.45	0.15
Total carbon by combustion in a section of the bar....	0.78	0.35

The first layer or skin showing the very low carbon by colour test gave a very large quantity of black insoluble matter. At first this was thought to be amorphous carbon; further examination, however, proved it to be black magnetic oxide of iron. The total carbon present in this first layer was then ascertained by combustion, and the quantity found was in A, 0.16 per cent., and in B, 0.18 per cent., thus showing the surprising fact that the actual surface of the bar contains comparatively speaking a very small proportion of carbon. The highest carbon is immediately underneath, and then gradually decreases until the centre of the bar is reached. Of course, in cases of higher degrees of carburisation, there will be less and less difference between the surface and centre as the bar approaches saturation.

The first layer of low carbon steel is easily visible upon an etched complete section of a different bar from the two referred to above. The layer appears to be of such small thickness that very little weathering or rusting would remove it. To detect this first layer of low carbon steel it is necessary to examine a bar which has not rusted. Of course the etching merely shows that there is a first layer of something different from the rest of the bar, and it is highly interesting as a corroboration of the differences which I noticed chemically many years ago. I also show a very beautiful effect obtained by etching a section of an extremely high carbon bar, one containing close upon 2 per cent. of

carbon. This appears to indicate that the iron has reached a certain degree of saturation with a carbide, and then this or some other carbide has commenced to crystallise out in acicular needles, one of which you will notice is three-quarters of an inch in length.

The theory of the formation of steel by the cementation process appears to be fairly comprehensible if we picture the precipitation of amorphous carbon in such a way upon the surface of the bar as to bring the particles of carbon into perfect molecular contact with the iron, combination would then immediately take place. The carbide of iron thus formed upon the surface then slowly diffuses throughout the rest of the bar. The crude bars of iron have always a thin layer of scale or magnetic oxide upon them. This magnetic oxide during the process of cementation will become a thin layer of spongy steel. During the cooling it is possible that this layer of spongy steel will oxidise, and in doing so decarbonise the surface to a slight depth. This may account for the presence of the first low carbon layer which I have drawn attention to.

The alternate heating and cooling several times of a bar of iron embedded in charcoal at length develops an unmistakable layer of spongy metal, if the temperature has not been too high, which actually begins to peel away from the bar, and I show an excellent example of this.

In conclusion, I have not considered the probability of the formation of Mond's ferrocobonyl, $\text{Fe}(\text{CO})_5$, as of any importance in connection with the impregnation of iron with carbon in this process. Undoubtedly it must be present at the earlier part of the process. The temperature at which most of the impregnation takes place, however, is much too high to allow the ferrocobonyl to exist. The presence of this ferrocobonyl at the beginning of the process will account for the fact that the charcoal and the black dust which is always formed contains a considerable proportion of iron in the metallic state. The black dust contains about 25 per cent. mineral matters, the accumulated ash of the charcoal, and 3.9 per cent. iron in the metallic state.

This paper was accompanied by many specimens illustrative of the facts described.

DISCUSSION.

The CHAIRMAN inquired whether the degree of conversion of the iron into steel depended upon the temperature or only upon the length of time that the iron remained in the converting chests. Was the temperature ascertained by a copper ball pyrometer or similar means, and did Mr. Hogg suppose that the temperature influenced the production of the blisters?

Mr. HOGG: The adjustment of the temperature is left entirely to the judgment of the workman, but trial bars are withdrawn from the chests and indicate how far the conversion has proceeded. The extent of the conversion of the iron into steel depends upon the length of time during which the heating is continued. The temperature would probably affect the size of the cavities, and masses of spongy steel, such as those exhibited occupying cavities, would fuse and run down when the temperature was raised.

Mr. JOHN PATTINSON said that the author had not touched upon the question of the form in which the carbon was conveyed into the iron, whether by the direct combination of the carbon of the charcoal or through the agency of a gaseous carbon compound. Since Dr. Percy published his well-known experiments on the subject a good deal of work had been done with reference to the decomposition of carbon monoxide by metallic iron and its oxides, and it occurred to him that these reactions probably played an important part in the process. The charcoal used would contain a good deal of occluded gas, chiefly air, and the oxygen in it would form carbon monoxide when the temperature was raised, and the black oxide on the outer portions of the bars would also give rise to some carbon monoxide, so that the atmosphere in the interior of the chests would consist chiefly of this gas. In his researches on the dissociation of the oxides of carbon by oxides of iron, Sir Lowthian Bell had obtained some remarkable results; by passing a current of carbon monoxide over oxide of iron he obtained deposits of carbon of over twice the weight of the iron employed, and the whole of this

carbon was due to the dissociation of carbon monoxide. He (Mr. Pattinson) had seen quite huge masses of carbon, over a cubic foot in bulk, deposited by a similar reaction in the flues leading from blast furnaces to the heating stoves, and these deposits had generally formed around pieces of iron that happened to be there. Again, in the bricks used as a lining for the blast furnaces themselves the 1 or 2 per cent. of iron in the clay acted in a similar way when exposed to the atmosphere of the upper part of the furnace, resulting in a deposition of considerable amounts of carbon in the substance of the brick itself. The bricks were permeated throughout with carbon and became swollen and quite friable and easily disintegrated. He was inclined to think that a similar reaction would take place in the converting chests and the decomposition of carbon monoxide, which begins below a red heat, would give rise to deposits of finely-divided carbon and from these the iron would take up its carbon and not directly from the charcoal. The whole subject was one of great interest and the members were much indebted to Mr. Hogg for bringing it before them.

Prof. Louis would like to ask Mr. Hogg whether he had ever analysed the gaseous contents of the blister cavities. Mr. Hogg had quoted the statements of Percy with reference to the origin of the blisters but with all due deference to the high authority of his old teacher, he (Prof. Louis) could not believe that ferrous silicate could be reduced by carbon in the absence of a base. He had never yet examined any sample of hammer- or roll-slag without finding in it a considerable amount of magnetic oxide and he would suggest that the blisters were due to gas formed by the reduction of magnetic oxide and not of ferrous silicate; it would be of interest to know whether this gas was carbon monoxide or carbon dioxide.

He quite agreed with Mr. Pattinson's suggestion as to the probability of the carbon penetrating into the iron by the deposition of finely-divided carbon from the dissociation of carbon monoxide; but even admitting that, there still remained the fact that solid iron and solid carbon combined together at a temperature much below the fusing point of the metal. With regard to the fact mentioned in the paper that the extreme outside of the converted bars was poorer in carbon than portions nearer the centre he thought that it might possibly be due to decarburisation having taken place subsequently to the conversion, during the gradual cooling down of the pot, and suggested that it would be of interest to quench a converted bar the instant it was sufficiently carburised, and to then ascertain the amount of carbon at different depths towards the centre of the bar.

Mr. Hogg in reply to Prof. Louis said that he was not aware that the gases from the blister cavities had ever been examined. It was a matter of considerable difficulty to secure a sample of the original gas, as many of the cavities communicated with the air, and in his own endeavours to collect the gases, he had never found either carbon monoxide or dioxide present, but only air, so that he did not for a moment suppose that his samples were in any way samples of the gases really contained in the cavities. With regard to Prof. Louis' objection to the theory based upon the reduction of ferrous silicate, there was no doubt that the black opaque globules found in a large number of the blisters were practically millinder and not ferrous silicate.

Meeting held May 14th, 1896.

On this occasion the President visited the Section, and was entertained at dinner. The proceedings of the meeting will appear in a subsequent issue.

MR. F. J. R. CARULLA IN THE CHAIR.

THE CORROSION OF IRON BY RAW TAR.

BY F. J. R. CARULLA.

COAL or gas tar is very extensively used for protecting from rust iron surfaces exposed to the weather, especially in chemical works where the atmosphere is more than normally destructive of this metal. This is the reason for bringing before you a remarkable example—or what appears to be one—of the danger that the careless or ignorant use of raw tar as a substitute for paint may entail. The two bolts here exhibited, originally 12 in. by 1½ in. thick, which are so thoroughly corroded as to present the appearance of having been soaked in some dilute acid for a considerable time were found in this condition when taken out of the valve boxes of a pump through which only water from a well for the general supply of the works had been passed. The bolts which act as stops to prevent the excessive rise of circular india-rubber valves were always completely immersed in the water. The only explanation of this corrosion that has been arrived at is that tar residues known to exist on the surface soil have communicated this undesirable property to the water in the well. A chemical examination confirms this. The water was found to be basic, which might be expected from its strong smell of naphthalene or gas liquor. It yielded on analysis:—

	Parts per 100,000.
Total solids at 110°	82
Free ammonia	0.43
Albuminoid ammonia	6.01
Chlorides expressed as chlorine	12.20
Carbonates expressed as CaCO ₃	22.00

This water has eaten into iron to the extent seen on the surface of these bolts which show indentations in places exceeding ¾ of an inch in depth. That this corrosive action is due to something communicated by the tar would appear to be indicated by the fact that similar bolts in a pump at

the same works used for raising tar, and that only, also show corrosion of a similar character although not quite so pronounced. The bolts in another pump, lifting river water in the same place, show no signs of corrosion, which goes some way to indicate the common origin of the damage in the two other cases.

From a consideration of the analysis of the water given above, one may reasonably suspect that the presence of ammonium chloride, a considerable constituent of some gas liquors and which therefore must be frequently present in crude tar, may contribute to the corrosive properties of this water.

The remarkable character of the corrosion which is so much localised in various places leaving much of the surface of the bolts almost untouched suggests the formation of galvanic couples at a number of points in the neighbourhood of which the whole of the action has taken place. The oxide of iron that is sometimes present in wrought iron in the form of slag left between the laminae of which such iron is composed, may account for this peculiarity.

Whatever the exact explanation may be, the examples before you certainly impress one with the necessity for neutralising the cause of this corrosion before using crude tar as a protection for iron surfaces. Cases could be cited of gas holders that have been quite damaged by having been coated with raw tar without preparing it in any way. A note abstracted from a German source and given on page 480 of the Journal of the Iron and Steel Institute No. II, 1892 is worth quoting as it describes how tar should be prepared for use on iron and is otherwise instructive.

"Raw tar is not adapted for use in coating iron. The coating produced rapidly scales away and destroys the metal, the action being due to the carbolic acid, which is present in the tar. If this tar, however, is heated with 2 or 3 per cent. of lime to neutralise the acid, it may afterwards be used without injury to the iron, and at the same time give a satisfactory coating to the metal."

It will not escape notice that carbolic acid is here given as the injurious constituent whereas the contaminated water first referred to is of a basic character. As ammonia is also generally present in tar it is not unreasonable to suppose that lime possesses a permanent neutralising power for the acid that the volatile alkali does not possess.

It is almost superfluous to add that the carbolic acid so injurious to iron is the very thing wanted for the protection of wood. Therefore when coating with tar a railway tank wagon for example, the proper method would seem to be, first to coat the iron-work with tar that has been heated with lime in the manner described and after that to coat the wooden frame work with raw tar.

DISCUSSION.

Mr. F. CLOWES questioned the accuracy of the inference that carbolic acid was the active agent in the corrosion of iron by crude tar.

Mr. L. ARCHBUTT mentioned a case in which creosote had leaked into an iron boiler and corrosion certainly did take place.

Mr. G. J. WARD said that galvanised sheets corroded

rapidly if coated with tar as usually applied, *i.e.*, simply heated to drive away the ammonia.

Mr. JOHN WHITE said that the analysis of the water that caused the corrosion showed only 0.43 part per 100,000 of free ammonia, whilst the chlorine as chlorides amounted to 12.20 parts. He was hardly disposed to think that under the circumstances any importance could be attached to the presence of ammonium chloride in the water. The amount of carbonate of lime was rather high, being 22 parts per 100,000. The corrosion of the bolts was very similar to that in the spout of a kettle that he once saw, and which he suggested might be produced by the action of dissolved carbonic acid gas. It might be that the action upon the bolts was due to the same cause. Ordinary kettles were only tinned in the body, the spout not being tinned. As this was an isolated instance it could not be attributed to galvanic action from contact of two dissimilar metals, for were this the case the spouts of all similar kettles would corrode in the same manner.

Mr. F. J. R. CARULLA said he concurred in the opinion that the question presented difficulties, but he had been induced to bring the subject forward on account of its practical importance.

AN EVAPORATION TEST FOR MINERAL LUBRICATING OIL.

BY L. ARCHBUTT, F.I.C.

THE usual method of determining the volatility of mineral lubricating oil is to place a weighed quantity of the sample of oil in a shallow dish or watch glass and expose it in a water or air oven for a certain number of hours, noting the loss of weight. But as the result of such a test must vary according to the number of times the air of the oven is changed during the test, a better plan is to place the receptacle containing the oil in a tube and pass a definite current of air or steam through the tube.

The apparatus which I use (Fig. 1) consists of a straight copper tube, $\frac{7}{8}$ in. internal diameter and 2 ft. long, having a

Fig. 1.

EVAPORATION TEST APPARATUS FOR MINERAL LUBRICATING OIL. One-sixth size.

branch tube, $\frac{3}{8}$ in. diameter and about 10 ft. long, entering it near one end, coiled around the straight tube as shown in the figure. This tube and coil are fixed in a rectangular air oven of tinned sheet iron, lagged with asbestos millboard to reduce radiation, and heated by a row of small gas jets. A thermometer is fixed in the oven. The ends of the wide tube which project beyond the oven are closed by brass screwed caps, one of which, at the opposite end to the branch tube, is perforated, and carries a narrow tube in the centre. Air or steam admitted to the coiled tube, after becoming heated in the coil to the temperature of the oven, passes over the oil in the wide tube and out through the short tube in the cap. The oil is contained in a platinum tray, 3 in. long by $\frac{1}{2}$ in. wide by $\frac{1}{4}$ in. deep, which for convenience of manipulation is placed in a glass tube which just slides within the copper tube and serves as a carrier.

The quantity of oil used for a test is 0.5 gm., which forms a thin layer at the bottom of the platinum tray. The temperature of the oven is varied to suit the requirements of the test; for cylinders working at 160 lb. pressure, the oil should be tested at 370° F. The gas passed through the tube may be either air or steam, and of course the speed and volume of the current must be approximately the same in all cases to give comparative results. In my own case having a supply of compressed air, I reduce it to a constant

current of 2 litres per minute by means of the simple regulator shown in Fig. 2, and I expose the $\frac{1}{2}$ gm. of oil to this current for exactly one hour. The compressed air enters the regulator at A (Fig. 2), and a slight excess is kept continually escaping at the lower end of the wide tube B which is immersed to a depth of 3 in. in water. The supply is taken from the branch C, the orifice of which is reduced until just large enough to pass 2 litres per minute against atmospheric pressure under the 3 in. head of water.

If steam be used instead of air, the inlet (Fig. 1), is connected to a flask or boiler, and the exit to a Liebig's condenser. The gas under the boiler is regulated so as to distil a definite volume of water in the hour, 100 c.c. being a convenient quantity, though 92 c.c. is the volume required to give a current of steam nearly equal to the above-mentioned air current. The boiler is then detached, all the steam is blown out of the apparatus, and the platinum tray containing the oil is inserted. After allowing a few minutes for the tray of oil to become heated up, the steam current is turned on. If the tray be inserted without first blowing out the steam, water condenses on the platinum tray, the oil creeps over the edge of the tray, and the test is spoiled.

The figures given in the table show, with five different samples of pure hydrocarbon oil, the kind of results obtained by this test. Bearing in mind the fact that the volume of steam passed over the oil in these experiments was about 8 per cent. in excess of the volume of air, the average loss of weight is very nearly the same in both gases, thus:—

AIR CURRENT REGULATOR. Quarter size.

EVAPORATION TESTS OF MINERAL LUBRICATING OILS.

DISCUSSION.

Mr. J. M. C. PATON asked if it were certain that both the air and the superheated steam were brought up to the same

temperature? Unless there were a large excess of heating surface there would be a possibility of air and steam not

attaining exactly the same temperature, owing to their different capacities for taking up heat.

Mr. L. ARCHBUTT explained that a very large excess of heating surface had actually been given, and, as a matter of fact, thermometers showed the full temperature was always attained.

Dr. F. CLOWES said it would be noticed that the flashing point was not a measure of the volatility of the oil as determined by Mr. Archbutt's method. There seemed to be absolutely no relationship between them, and it was evidently impossible to infer the general volatility of an oil from its flashing point. In the tabulated statement it would be seen that an oil with low flashing point might show a considerably less loss by volatilisation than another oil which possessed a higher flashing point. There was a similar want of connection between the specific gravity and the volatility as measured by the loss of weight suffered by the oil in an air current at high temperature. This was apparently due to the fact that all these hydrocarbon oils were mixtures of different oils, and contained very variable proportions of heavy and light oils. Accordingly, one oil might consist mainly of heavy oils with high boiling point together with a little very light and volatile oil: such an oil would have a high specific gravity, low flashing point, and low loss in the air current; while another oil containing but little heavy oil and much oil of medium specific gravity would show a high flashing point and greater loss by volatilisation. These considerations pointed to the value of Mr. Archbutt's test.

Mr. G. J. WARD said that Mr. Archbutt, in his paper, stated that he passed 2 litres of air per minute through the oven, but he gave no information as to how he measured the quantity of air. It seemed somewhat difficult to put an appliance for measuring the air on the delivery tube C without causing back-pressure at that point, with the result that less air would pass through C. Perhaps Mr. Archbutt would explain how the air was measured, so that any other person putting up a similar apparatus could obtain figures which would be absolutely comparable with his.

Mr. L. ARCHBUTT said the air current was measured by connecting the exit C to a bell-jar of known capacity, full of water, sunk in a bucket of water. As the air passed into the bell-jar it was gradually raised so as to maintain the same water level within and without the jar.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman:* Thos. Fairley. *Vice-Chairman:* Christopher Rawson. *Committee:* J. Cohen, J. R. Denison, T. Glendinning, F. W. Richardson, and A. Smithells.

Meeting held at the Queen's Hotel, Leeds, on Monday, April 27th, 1896.

MR. C. RAWSON IN THE CHAIR.

"CACHOU" DE LAVAL.

BY F. W. RICHARDSON, F.C.S., AND H. E. AYKROYD.

THE title of our paper will convey to the uninitiated but little idea of the nature of the substance in question. "Cachou de Laval" is not a sweetmeat or dietary article, but a very remarkable dyestuff made in so peculiar a manner that it may be said to stand alone in the category of colouring matters.

According to the patent of Croissant and Bretonnière, dated April 24th, 1873, the substance we now term "Cachou de Laval" is obtainable by the fusion of a large number of organic substances with alkaline sulphides. The provisional specification with characteristic amplitude includes a very wide range of organic bodies extending from the carbohydrates, starch, cellulose, and sawdust, to such nitrogenous substances as blood, horn, and feathers.

Waste or spent dyewoods are said to be advantageously utilised by this process. Sodium polysulphide is the alkaline sulphide preferred, and this is made by boiling down a mixture of sulphur and a solution of caustic soda. The heat of fusion gives a latitude of 100° C. to 350° C. according to the nature of the substance used and the tint that it is desired to obtain.

We have sought for any literature upon the constitutional nature of "Cachou de Laval," but with only a negative result, indeed, all that seems to have been discovered is contained in the original specification, dated 23 years ago, and there it is stated:—"It is believed that the combination which is developed in this operation, constitutes an organic sulphide. The products obtained by this process are in fact the result of a real combination. Thus if wood sawdust for example be mixed with a solution of potassium sulphide, and the temperature be raised, it will be observed that sulphuretted hydrogen is abundantly evolved, especially when a temperature of about 300° centigrade is obtained. The alkaline sulphide has therefore become decomposed. A portion of its sulphur has taken possession of the hydrogen of the organic body, and the carbon which remains is in a state of particular combination."

It will easily be understood that the reaction is of a very irregular character, and that unless due attention is paid to fixity of conditions and to similarity or identity of substance, colouring matters giving very variable shades will be obtained. "Cachou de Laval" occurs in black porous hygroscopic lumps, quickly alterable by exposure to the air.

It dissolves readily even in cold water, giving a black solution developing brownish colours by aerial oxidation. The dye is substantive and all that is necessary is to immerse the cotton in a solution of the "cachou" at about 60° C., using salt, or still better, bisulphite of soda as an assistant. In from 20 to 25 minutes the desired shade is obtained. To fix the colour, the cotton is worked for a short period in a solution of bichromate of potash, or in a bath containing either sulphate of copper or sulphate of iron. Shades varying from a pale grey to a brownish black may thus be obtained. We find that "cachou" makes an excellent bottom colour and the shade blends well with the ordinary artificial dyes.

Our inquiry into the nature of this very complex dyestuff has been much further prolonged than we could ever have anticipated. At the very outset we were confronted with the unreliability of existing processes for estimating the sulphides, sulphates, and thiosulphates present, and it was only when we had concluded the investigations reported in the March number of this Journal that this difficulty was overcome. It will readily be seen that the estimation of sulphur salts in a very black alkaline solution, readily changeable even by mere exposure to the air, is not a very easy task. As a general outline of the method we adopted may be of interest and use to chemists we will enter into a few details.

The dye-radical is fortunately completely precipitated by zinc-ammonium-chloride which also removes from solution the whole of the sulphides and polysulphides. The clear colourless filtrate now readily lends itself to our special method described in the March number of this Journal (1896, 171).

The ammonia is neutralised by dilute hydrochloric acid in the presence of methyl orange, and the resulting solution, after being made to a definite volume, is titrated upon N_{10} iodine. After this operation the solution remains quite neutral showing the entire absence of sulphides. It was only subsequent to this discovery that we noted that sulphur when fused with caustic alkalis gives mixtures of polysulphides and thiosulphates, no sulphite being formed (Watts' Dict. of Chemistry—Morley and Muir).

"CACHOU DE LAVAL."

These patterns have been dyed with "Cachou de Laval," made by fusion of the substances named (excepting "Cachou de Laval" itself) with sodium polysulphide :—

1.—Milk sugar, 5 per cent.

5.—Sawdust, 5 per cent.

2.—Cane sugar, 5 per cent.

6.—Furfurol, 5 per cent.

3.—Tartaric (oxysuccinic) acid (as sodium tartrate),
5 per cent.

7.—Thiophene, 5 per cent.

4.—Succinic acid (as sodium succinate), 5 per cent.

8.—"Cachou de Laval," 12½ per cent.

The sulphates were readily estimated in another portion of the zinc-filtrate by our tartaric acid process.

The carbonates were separated in the form of BaCO_3 by precipitation with BaCl_2 , the precipitate, after being well washed with boiling distilled water, being treated with HCl and the evolved CO_2 endiometrically determined.

The hydrate appeared in the filtrate from the precipitation with BaCl_2 ; by strongly colouring the somewhat greenish solution with phenolphthalein a titration with $\frac{N}{10}$ HCl was easily affected.

The sulphides and poly-sulphides were determined in the zinc precipitate, which was boiled with dilute HCl in connection with a condenser; all the SH_2 evolved being condensed in ammonia solution, which then gave very delicate indications with Schwarz's standard zinc-ammonium-chloride solution. The free sulphur left in the distilling flask by the decomposition of the polysulphide of zinc was collected with the dye-radical upon a filter and, by subsequent "soxhletting" with CS_2 , was easily determined.

To ascertain the amount of pure dye-radical present necessitated a process which was only developed after repeated experimental failures.

The solution of the "cachou" was filtered, an operation requiring strong paper and a force pump, and the dye left in the paper was removed by washing with solution of caustic soda; by treating the filtrate with excess of HCl and boiling, a precipitate containing the radical with large excess of sulphur was obtained.

To remove the free sulphur the precipitate was thoroughly washed to remove free acid and mineral impurities; it was then dried and "soxhletted" with CS_2 . It was found necessary to grind the dried precipitate to an impalpable powder, and to "soxhlet" some 200 times with CS_2 to obtain a pure result.

The results of our analysis of "cachou" are now submitted for your consideration.

"Cachou de Laval."

Moisture	1.60
Sodium polysulphide (Na_2S_x)	10.50
" thiosulphate ($\text{Na}_2\text{S}_2\text{O}_3$)	19.62
" sulphate (Na_2SO_4)	3.15
" sulphite	None
" chloride	1.20
" carbonate	49.80
" hydrate	1.12
" "cachouate" (dyestuff)	19.00
Insoluble organic impurities, &c. (by difference)	1.60
Ferrous oxide	0.50
Aluminium oxide	1.35
Magnesium oxide	0.16
	<u>100.0</u>

These data are somewhat surprising, inasmuch as they show the presence of what may appear to the uninitiated to be a large proportion of saline impurities, but we must observe that sulphides and thiosulphates are agents essential to the solution and preservation of the dye itself. Solutions of "Cachou de Laval" speedily give a considerable separation of sulphur under aerial influences, and the polysulphides thus gradually decomposed utilise the oxygen which might otherwise too readily attack the colouring matter.

The amount of carbonate of soda would seem to be excessive, but is no doubt unavoidable when we take the mode of manufacture into account.

The Nature of the Dyestuff in "Cachou de Laval."

Our entire stock of information from outside sources as to the nature of the dyestuff present in "cachou" amounted to certain vague statements as to its being an organic sulphide, and a derivative of mercaptoic acid; indeed the proprietors (the St. Denis Société anonyme of Paris), who have very kindly answered a number of questions on the subject, state that "literature says nothing about the formula and constitution."

We were pleased to find that the dyestuff is not one of the mercaptans, the vile odours of this class of bodies being potently in mind. It was also easy to ascertain that mercapturic acids (acetyl compounds of alkyl thio-lactic acids)

(Ber. 18, 258) were absent. Methyl and ethyl groups were absent, and it was therefore evident that no thio-ethers or thio-alcohols were present. The pure dyestuff or radical was only obtained in a pure state after repeated treatment with hot dilute HCl and with hundreds of Soxhlet extractions with CS_2 , the free sulphur being tenaciously held by the hard gritty particles of the dried organic colouring matter.

The colour principle thus obtained is a black powder burning almost like sulphur itself when heated. It is quite insoluble in water, alcohol, ether and acids, but dissolves in hot solutions of caustic soda and potash with the production of colours varying from dark green to greenish-black. These solutions become rapidly brown in the air.

The estimation of sulphur was effected by fusion of the dye principle with over 40 times its weight of a mixture of carbonates of potash and soda and nitrate of potash in about equal proportions; the mixture in the platinum crucible being covered with a layer of potassium carbonate. The barium sulphate subsequently obtained amounted to over four times the weight of the dye taken.

The ultimate organic analysis was undertaken in the knowledge of the presence of so large a quantity of sulphur. Ignitions were made after mixing with large proportions of nitrate of potash in an iron boat placed in the combustion tube, but it was found that nitrogen oxides were evolved, and even a heated layer of copper turnings did not sufficiently prevent their egress.

The chromate of lead method was finally adopted, and this gave very concordant results, every trace of sulphur being oxidised and retained in the combustion tube in the form of lead sulphate. All the combustions were made in a slow stream of air drawn by a filter pump through the tube after all moisture and CO_2 had been removed by passing the air through a series of chloride of calcium tubes and potash bulbs.

The following figures express the average results of several very concordant analyses:—

Sulphur	66.00
Carbon	31.40
Hydrogen	1.30
Oxygen	1.30
	<u>100.00</u>

The empirical formula of this compound is therefore $\text{C}_{33}\text{H}_{16}\text{S}_{26}\text{O}$, and its molecular weight is 1260.

To determine the valence of the radical was not an easy task, for we have to deal with a body insoluble in all ordinary solvents. It seemed to us that the property which the soda salt of the dye possesses for precipitating zinc and silver from ammoniacal solutions would serve us in good stead.

The pure dyestuff was heated with a freshly-prepared carbonate-free caustic soda solution; after filtration the solution was precipitated with ammonium-zinc chloride in one instance and with ammoniacal silver nitrate in another set of experiments. The thoroughly washed and dried precipitates gave us the zinc and silver salts respectively, and the amounts of zinc and silver found in these salts gave us the necessary data for ascertaining the valence of the radical.

	Zinc Salt.	Silver Salt.
Zinc	26.0	
Silver		54.2
Radical	74.0	45.8
	<u>100.0</u>	<u>100.0</u>

The zinc salt therefore indicates that the molecular weight of the radical $\text{R}^{\text{II}}=185$ or $\text{R}^{\text{I}}=92.5$.

The composition of the silver salt shows that the radical $\text{R}^{\text{I}}=91.3$. These two results are therefore quite harmonious.

Unfortunately we had not sufficient of these salts to determine their degree of oxidation, but this may have been more considerable than that of the radical analysed; thus the molecular weights are greater than that of the oxygen-free base.

In this experiment one third of the sulphur was eliminated as sulphuretted hydrogen and a large amount of the dye was obtained. According to Fischer's researches lactose is thus constituted:—

and the large number of (CH.OH) groups present in this body and in carbohydrates generally would appear to be a very desirable feature for the production of the trithiophenates (*i.e.*, of "eachou").

Cane sugar, starch and sawdust also give large yields of the dye and the results upon cotton hanks from these and all the other substances experimented with we submit for your examination. We have treated the hanks with bichromate of potash and blue vitriol respectively, in order that you may see how closely the shades obtained correspond with those yielded by the commercial "eachou" itself.

As it was suggested to us that almost all hydrocarbons would give (CS) groups and eachou on fusion with polysulphides we experimented with the saturated hydrocarbons, particularly with paraffin wax, and with different members of the aliphatic (fatty) series, but in every case with a negative result.

Also formates, acetates and oxalates gave us no particle of "eachou," and from these facts it is evident that compounds of the general formula C_nH_{2n} and $\text{C}_n\text{H}_{2n}\text{O}_2$ are not "eachou"-formers.

It would appear that just in proportion as an organic body contains carboxyl groups, to that extent its powers of forming trithiophenates are weakened.

It is also noteworthy that while succinic acid—

gave us a fairly large yield of "eachou," its congener, tartaric, *i.e.*, dioxysuccinic acid—

gave us scarcely more than a trace of the dye.

Mucic acid $\{\text{C}_4\text{H}_4(\text{OH})_4(\text{CO} \cdot \text{OH})_2\}$.

Pyrogalllic acid $(\text{C}_6\text{H}_3(\text{OH})_3)$ and gallic acid—
 $(\text{C}_6\text{H}_2(\text{OH})_3\text{CO} \cdot \text{OH})$,

although benzene derivatives gave a very appreciable amount of the dye; while, on the other hand, phthalic anhydride and sodium-benzene monosulphonate gave almost a negative result. These facts show that not all organic bodies yield eachou by polysulphide treatment, and that it is not a simple question of the formation and building together of CS or CSH groups.

We find that the tetramethenyl formation of the CH groups is peculiarly favourable to the production of the dyestuff, as is also the presence of CH_2 groups, and it is probably for this reason that succinic, mucic, and pyromucic acids give so much "eachou."

Furfural in reaction with the sodium polysulphide gave us no sulphuretted hydrogen, and from an analysis of the products formed the following appears to be the only equation possible:—

Furfural very readily gives a much larger yield of the "eachou" dye than any body (with the exception of thiophene) with which we have yet experimented, and there can be no doubt that the reaction thus given converts our supposition as to the composition of the dye-radical into proof. Thiophene, $\text{C}_4\text{H}_4\text{S}$, with the constitutional formula—

suggested itself as a body which under suitable conditions should give the dye on sulphuration. It is impossible to fuse such a volatile substance as thiophene with polysulphides; yet we have obtained by means of a special treatment an enormous yield of "eachou" from this body and have

established the equation—

We find that on treatment with strong sulphuric acid, both thiophene and pyrrol become almost solid and evolve heat and sulphur dioxide; the compounds thus obtained are no doubt sulphated and polymerised products and as they are non-volatile it is quite easy to alkalinise them and fuse with sodium polysulphide. It would appear that thiophene, for example, gives—

polysulphide treatment gives—

Pyrrol—

although a tetramethenyl compound contains triatomic nitrogen and may react differently to thiophene or furfural. From a few experiments on a small scale pyrrol has given us the dye, but we have yet to investigate the full changes which ensue.

The following equation would appear to be the most probable—

In drawing to a conclusion of our inquiry we would call attention to the reaction ensuing when polysulphides are fused with organic bodies as a distinctive test for tetramethenyl and other "eachou"-forming groups in compounds, and for chemists with the time and the necessary apparatus the inquiry should prove very productive of useful results to chemical theory.

At a later time we hope to investigate the even more complex substances, so closely allied to "eachou," Vidal black and thiocatechin; dyestuffs of high excellence, as those engaged in the dyeing of cotton will allow. The introduction of the aromatic series with nitrogen (diamine) groupings enormously increases the complexity of these bodies.

Our best thanks are due to Mr. Frank Wood and Mr. Adolf Jaffé for valuable assistance in conducting this inquiry.

SUPPLEMENTARY NOTE.

In reply to a number of questions and criticisms, the authors state that:—

In obtaining the dye-stuff from thiophene the preliminary sulphation was not carried so far as to lead to the splitting up of the molecule. After mixing the thiophene with sulphuric acid in the cold the fluid was warmed to 100° F. for a few moments; as soon as solidification ensued the mass was treated with slight excess of caustic soda solution and then evaporated down (for ultimate fusion of the residue) with polysulphide of sodium.

Separate experiments showed that a soluble sulphated product constituted from equal molecules of H_2SO_4 and $\text{C}_4\text{H}_4\text{S}$ was formed; this soluble product gave a large yield of "eachou." It is true an insoluble body was also produced, but this was present in small quantity and gave none of the dyestuff.

Moreover we prepared thiophene α -sulphonic acid, using a 1 per cent. solution of the thiophene in ligroin for treatment with sulphuric acid; here there was certainly no splitting up of the molecule and the $\text{C}_4\text{H}_4\text{S} \cdot \text{SO}_3\text{H}$ (sodium salt) gave the "eachou" dye on fusion with Na_2S_4 . Furfural gave the dye by direct boiling and fusion with the polysulphide, and we regard this fact as weighty evidence in support of our views.

We are aware that furfural, thiophene, and pyrrol are regarded as analogous to benzene, but as the empirical formula of the "eachou"-dye-radical shows carbon in combinations of 4—or multiples of 4—atoms and as thiophene

and furfural act as parent substances for the production of "cachou" we cannot resist the conclusion that the tetramethenyl formation is characteristic.

The (C.O.H) group in furfural may be regarded in the same light as the O₂S and NH in furfuran, thiophene, and pyrrol respectively. We have made several ultimate analyses of the "cachou" radicle, and the results have been singularly concordant and conclusive.

Having carefully analysed the products of the action of sodium polysulphide on furfural we can give no other explanation of the facts than those given in the paper.

According to our researches, the "cachou" dyestuff is not a mercaptan (*i.e.*, a sulphhydrate or hydrosulphide of hydrocarbon radicle); in its pure form it certainly has not and does not yield malodorous effluvia characteristic of this class of bodies, and from reasons to be adduced the absence of alkyl groups precludes the possibility of its being a mercaptan.

The following are some of our reasons for supposing that the "cachou"-dye does not contain alkyl, &c., groups:—

(1.) The presence of so very small a proportion of hydrogen which is entirely replaced by bases.

(2.) Sulphated thiophene and thiophene sulphonic acids, furfural and sulphated pyrrol readily give the dye in large proportions, and these bodies do not contain any alkyl groups.

(3.) From C₁₂H₈S₂O₄.H and Na₂S₂O₄ we obtain a large yield of a body (dyestuff) containing—

S 66, C 31.4, H 1.3, (O 1.3);

surely there is no other interpretation than that which assumes the union of all the S with the C atoms, and this is according to analogy (*e.g.*, trimethyl-trisulphone, &c.).

It will be observed that the simplest statement of the molecular weight deducible from an analysis of the zinc and silver salts of the dye is somewhat different to that of the unoxidised dyestuff; we account for this by the fact that in the making of these metallic salts an alkaline solution of the dye was used, and the oxygenation may have been more considerable than that represented in the ultimate analysis. The data, with allowance for the oxygenation factor, are sufficiently near to support the empirical formula M₂.(C₄S₃)ⁿ.

H₂C₄S₃ is the simplest formula for the dyestuff, just as C₆H₁₀O₅ is the simplest formula for starch, &c. The heavy and solid character of the dyestuff shows that its full formula must be a high polymer of this group and can only be represented as (H₂C₄S₃)_n.

Kopp is said to have obtained "cachou" from sodium acetate, yet we have never yet succeeded in obtaining a particle of "cachou" from this body; all we obtain is a greenish-black liquor which on standing a few hours gives a clear yellow supernatant liquid and a dark black sediment. Attempts at dyeing show that the colour obtained is not a dye.

DISCUSSION.

Mr. C. RAWSON remarked that "Cachou de Laval" was a substance of great interest in the dyeing industry, and that he was somewhat surprised that it was not used more extensively, though doubtless the comparatively high price at which it had been sold had something to do with this. He was convinced that the class of dyes to which it belonged, including Vidal black and thiocatechin, would be of great importance in the future. He asked whether the products obtained from thiophene and furfural had been analysed, or whether the dyeing test alone had been considered sufficient to prove their identity with the colouring matter of "cachou." He also pointed out that "Cachou de Laval" deteriorates somewhat rapidly if not preserved in well-closed vessels; and asked the authors if they had examined the products formed.

Mr. T. FAIRLEY asked the authors whether they had included any aldehydes or ketones among the organic substances from which they had attempted to obtain "Cachou de Laval," since it is known that these bodies readily yield sulphur compounds. He also suggested that it would be of interest to try the action of sulphur on paraffin, pushing the heating as far as possible.

Mr. H. R. PROCTER inquired whether there was any possibility of thiophene being used on the commercial scale in making the dye.

Mr. F. W. RICHARDSON, replying, said that Mr. Aykroyd and himself had analysed the different substances obtained from thiophene, furfural, and pyrrol. They had further proved their identity with the colouring matter of "Cachou de Laval" by means of what appeared to be a characteristic test for that substance, viz.: if the colouring matter be dissolved in excess of baryta water and the barium then precipitated by a current of carbon dioxide, a blood-red solution remains; all the substances gave this reaction. They had also dyed cotton with each of the substances in sulphuric acid, chrome, and copper sulphate baths, and obtained the same shades from all of them.

The price of thiophene was far too high to make any commercial application possible.

They had found that the deliquescent substances contained in "Cachou de Laval" caused it to absorb moisture from the air rather rapidly (as much as 18 per cent. in a night), and that accompanying this an oxidation took place which first caused the colouring matter to dye browner shades and then diminished its colouring power very considerably.

In reply to Mr. Fairley he said that they had used aldehydes in their experiments, but had found that the methyl and other alkyl groups were not "cachou"-formers, and had therefore not considered it to be worth while to try ketones.

Meeting held on May 8th, 1896.

On this occasion the PRESIDENT visited the Section and was entertained at dinner. The proceedings of the meeting will appear in a subsequent issue.

Meeting held in Glasgow on Tuesday, March 3rd, 1896.

DR. JOHN CLARK IN THE CHAIR.

EXPERIMENTS WITH BORDEAUX MIXTURE AS A PREVENTIVE AGAINST POTATO DISEASE.

BY JAMES HENDRICK, B.Sc., F.I.C.

ONE direction in which chemistry has been of service to agriculture has been in the provision of preventives against and remedies for the insect and fungoid pests which are among the most troublesome foes of the farmer. Bordeaux mixture is a preventive. It was first used about 13 years ago, in the *claret* district in France, as a preventive against mildew and other fungoid diseases of the vine. It has since been tried, especially in the United States, upon a great variety of plant diseases, and in many

eases with marked success. It has, in fact, been steadily gaining for itself the position of the most generally useful agricultural fungicide known. In Britain it is practically known only as a preventive against potato disease, which is due to the ravages of the fungus *Phytophthora infestans*. It was used against this disease in France very soon after its discovery, and since then its use has been extending in all parts of the world. Bordeaux mixture is prepared by adding lime to a solution of copper sulphate until the copper is completely precipitated. There have been a great many modifications in the formula used in making the mixture. Solutions of copper sulphate of all strengths have been used, from those which, when precipitated, give a paste, to quite dilute solutions. But for potato disease the generally recommended strength contains 2 lb. of copper sulphate in 10 galls. of the mixture, and is commonly known as the 2 per cent. mixture.

In making the mixture an excess of lime is used so as to ensure not only the complete precipitation of the copper, but that the liquid shall be strongly alkaline. If copper be left in solution, the foliage of the potato plant itself will be injured. The reaction which takes place is commonly represented by the equation—

That is, 249 parts, by weight, of crystallised copper sulphate require, for complete precipitation, 74 parts of pure slaked lime. The chemistry of the change is not, however, quite so simple as is here represented.

If lime be added to a solution of copper sulphate in quantity not sufficient to precipitate all the copper as hydrate, we get a sea-green precipitate containing basic sulphates of copper. Though we may completely remove the copper from solution in this form, it cannot safely be used for Bordeaux mixture. On exposure to the air, carbon dioxide is absorbed, forming some copper carbonate, and liberating some of the copper again in a soluble state as sulphate. If, again, lime be added in excess, we get an azure blue precipitate, which contains all the copper, chiefly in the form of hydrate. The liquid remains alkaline, and, on standing, the precipitate gradually turns almost purple in colour. It is as the azure blue precipitate that Bordeaux mixture should be used. When this is done, the copper sticks firmly to the leaves of the plant, yet it does not injure them. In my own experiments the copper could still be detected on the leaves of the plants weeks after application, although extremely rainy weather, July and August 1895, had intervened. The precipitate ought not to dry to powder and shake off, nor should it wash off with rain, nor should it injure the leaves. In fact the sprayed foliage generally remains green longer than that which is unsprayed. It is probable that some of the inconsistent results which have been obtained with Bordeaux mixture are due to improper preparation of the mixture. Farmers are not generally chemists, and common lime, such as farmers would use, is generally very impure, and might be to a considerable extent turned into carbonate as well. It is generally recommended to use 1 lb. of slaked lime to every 2 lb. of crystallised copper sulphate. This should give a very considerable excess of lime, but I can quite imagine cases arising where the copper is either not completely precipitated or is precipitated in the green state. On this account, and on account of the general aversion of farmers to the trouble of making up a chemical mixture of this kind, which they do not understand, various dry powders of the nature of Bordeaux mixture precipitate have been placed upon the market, and great success is claimed for them.* These have simply to be stirred up in water and sprayed upon the plants.

It is in Ireland that Bordeaux mixture has had its most extensive and successful use in the British Isles. The Irish Land Commission, Agricultural Department, early took the matter up, and have since published annual reports on the subject. The result has been that the use of this fungicide is far better known in Ireland than in either Scotland or England. In Scotland, experiments have been

made from time to time but the results obtained have been very indecisive. This may be partly due to the fact that owing to the use of better and stronger varieties of potato, disease is not nearly so prevalent in Scotland as in Ireland, where this preventive has been found so effective.

Early last year I arranged to have experiments carried out on this subject on Woodilee Farm, Lenzie, by Mr. Weir, the manager; and on Newton Farm by Mr. John Speir. On Woodilee Farm, five plots, and on Newton Farm, six plots, each $\frac{1}{10}$ th of an acre in area, were marked off. The land was chosen as even and free from inequalities as possible. The same variety of potato, Red Bog, was grown on both farms. This potato was chosen as it is one which is very liable to disease. All the plots were treated in every way alike, except in respect of the spraying. Four plots were sprayed. Two of these were sprayed once, and two were sprayed twice. The mixture was made up of two strengths. One contained 2 lb. of crystallised copper sulphate to 10 galls. of water, this will be referred to as the 2 per cent. mixture; the other contained $1\frac{1}{2}$ lb. of copper sulphate to 10 galls. of water and will be referred to as the $1\frac{1}{2}$ per cent. mixture. Each of these mixtures was applied to two plots. The arrangement of plots was as follows:—

1. Unsprayed.
2. Sprayed once with the 2 per cent. mixture.
3. Sprayed twice " "
4. Sprayed once with the $1\frac{1}{2}$ per cent. mixture.
5. Sprayed twice " "
6. Unsprayed.

At Newton the first spraying took place on July 22, the second on August 8, and the potatoes were raised on September 23. At Lenzie, the first spraying took place on July 30 and 31, the second on August 26, and the potatoes were raised October 7 and 8. So far as could be seen, the spray in no way injured the foliage, but neither did it seem to have the effect which has been reported in many other cases,* of causing the foliage to remain green longer than in the unsprayed parts. No disease was noticeable on either farm before the second spraying, either on the unsprayed or on the sprayed plots. In fact, on both farms there was very little difference to be seen between the sprayed and the unsprayed plots at any time. When the leaves began to fall there was no visible difference between the plots, and on both sprayed and unsprayed plots the leaves fell at the same time. The sprayer used in both experiments was a Vermorel Knapsack sprayer.

In both experiments the shaws at the time of the first spraying were very big, and it was not only difficult to make sure that all parts of the foliage were thoroughly sprayed but it was almost impossible to avoid more or less injuring the plants in moving about among them. At the second spraying the foliage was already going down, and was not therefore so liable to injury.

When the time for raising came Mr. Speir found that he could with difficulty spare hands necessary for the long and tedious work of picking all the potatoes from the plots over by hand in order to remove the diseased tubers, and as there was so little sign of disease in the shaws, it was evident that there could not be much disease present. For these reasons, and because there was very little difference apparent between the plots, it was decided to raise one-quarter pole from each plot, pick over the potatoes from these and weigh them. As it was found on doing this that there was little difference in the proportion between diseased and sound tubers on the sprayed and on the unsprayed plots, and the evidence of the eye was thus confirmed, the whole plots were not weighed. It is to be noted that this is the method which has been followed in calculating the results of many of the experiments carried out by the Irish Land Commission and others. Though large plots were sprayed, only a small portion of each was picked over and weighed. The weight of potatoes, of a size too great to pass through a $1\frac{1}{2}$ -inch riddle, divided into diseased and sound, and

* See, for example, report of experiments conducted by the Irish Land Commission during the season of 1895. Blue Book C.—5028.

* See Bulletin No. 6, the U.S. Department of Agriculture, Division of Vegetable Pathology; the Journal of the Royal Agricultural Society of England, 3rd Series, Vol. III.; and the Irish Land Commission's Reports.

calculated to weigh per acre, found by weighing these small plots, is given in the following table :—

NEWTON. WEIGHT OF POTATOES PER ACRE.

Plot.	Sound.		Diseased.	
	Tons.	Cwts.	Tons.	Cwts.
1	9	0	1	17
2	6	3	1	6
3	6	11	1	7
4	6	11	1	14
5	10	3	0	9
6	7	13	2	6

It will be seen from this table that, though the proportion of diseased potatoes is somewhat less on the sprayed than on the unsprayed plots, the result is very unsatisfactory. Plot 5 is the only one on which the diminution of disease is sufficient to make the spraying worth while. It is to be remembered that no reliance can be placed on the weights per acre given here, as the plots raised were far too small to give accurate figures.

At Lenzie the whole of the plots were raised by hand. The potatoes were then thoroughly picked over by hand, and all the diseased ones separated. Every single potato from the whole of the plots was individually examined. The sound potatoes were then put through a riddle of $1\frac{1}{2}$ -in. mesh, and divided into marketable and small. The potatoes from each plot were thus divided into three lots: diseased potatoes, and large and small sound potatoes. Each of these lots was separately weighed. This work, which occupied a considerable number of hands for two days, was all conducted under the personal supervision of Mr. Weir and myself.

The following table gives the weight of potatoes of each kind from each of the plots, calculated to tons per acre :—

LENZIE. WEIGHT OF POTATOES PER ACRE.

Plot.	Sound Potatoes.			Diseased Potatoes.	Total Sound and Diseased.
	Large.	Small.	Total.		
	Ts. Ct. Qs.	Ts. Ct. Qs.	Ts. Ct. Qs.	Ts. Ct. Qs.	Ts. Ct. Qs.
1	6 5 0	1 13 1	7 18 1	1 9 0	9 7 1
2	6 0 0	1 14 2	7 14 2	1 2 2	8 17 0
3	6 7 2	2 2 3	8 10 1	0 7 2	8 17 3
4	6 0 3	1 15 2	7 16 1	0 12 3	8 9 0
5	6 0 2	1 17 2	7 18 0	0 13 2	8 11 2

The diseased potatoes were, as a rule, only slightly attacked by the fungus. Comparatively few were badly rotted with it, and these few were mainly to be found in plots 1 and 2. Indeed, there was very little sign of disease at any time in the shaws, and any disease which attacked the plots must have come pretty late. It is to be seen that in this case the sprayed plots are with one exception, plot 2, nearly free from disease. The explanations of the fact that plot 2 has much more disease than the other sprayed plots is probably to be found in the conditions under which it was sprayed. It was the first plot sprayed. Not only was the man who did the work quite unused to the machine, but something went wrong with the nozzle, and it was only with great difficulty that the spraying of this plot was finished at all on the 30th July. The nozzle was then repaired, and the other plots were successfully sprayed on the next day, 31st July. It is probable, then, that this plot was very imperfectly sprayed. It contains rather fewer diseased potatoes than plot 1, but three times as many as plot 3, which was sprayed twice with the same mixture. The $1\frac{1}{2}$ per cent. mixture does not appear to have been quite so effective as the 2 per cent. mixture. It is curious, too, that plot 5, which was sprayed twice, does not contain less disease than plot 4, which was dressed once only.

We have found, then, in this experiment that the application of the spray has diminished disease to a marked extent, but we are still in disagreement with the experiments of the Irish Land Commission, and others, on a most important

point. It has been almost universally found that the application of Bordeaux mixture increases the value of the crop not merely by diminishing the weight of diseased tubers, and hence increasing in proportion the weight of sound ones, but also by increasing the total weight of the crop. This action may be due to the spray preventing the early decay of the shaws through the ravages of disease. The leaves are first attacked by the fungus, and it is only by propagating itself from them through the stems that the pest finally reaches the tubers. So that if the shaws are early carried off by disease the formation of a heavy crop of tubers may be prevented, although such as are sound may to a large extent never be reached by the fungus.

In this experiment we have no greater weight of sound potatoes produced by the spray than by the unsprayed plots. This can be understood, however, when we remember that any disease which was present only appeared very late when the shaws were beginning to go down in the natural order of things, and when it was therefore impossible that the presence or absence of disease, could have much effect on the weight of crop produced. But this does not explain the curious fact that the total crop is greater on the unsprayed than on any of the sprayed plots. In fact the spraying, while it has diminished the weight of diseased potatoes, has not increased the weight of sound ones.

These experiments then, like all others previously conducted in Scotland, give unsatisfactory results. As in both the Old and the New Worlds the general results obtained with this fungicide have been so good, further experiment seems necessary to explain its comparative failure in this country.

In conclusion I must thank Mr. Weir and Mr. Speir for placing their land and labour at my disposal, and for the cordial and enlightened way in which they co-operated with me in carrying out these experiments. In this country the agricultural chemist has seldom land or means at his disposal of carrying out these large scale experiments, and he is entirely dependent on the public spirit and enlightenment of private individuals. These gentlemen, who are busy practical farmers, deserve the fullest recognition for the trouble and care which they have taken in assisting me with this work. It was only through them that I was able to carry it out at all.

DISCUSSION.

THE CHAIRMAN said they were very much indebted to Mr. Hendrick for bringing this matter before them, because, whilst agricultural papers were not very often brought before the Society of Chemical Industry, anything dealing with such an important question as the potato disease was certainly of great interest. He asked if the sulphate of copper used was absolutely pure; if not, it would contain more or less protosulphate of iron, which was not beneficial to the soil. Mr. Hendrick advocated the introduction practically of copper into the plant. Analysts had frequently to determine the percentage of copper in the plant, and whether this copper had been introduced artificially or naturally. The question whether copper might be thus introduced into the plant would require to be settled. Mr. Hendrick purposely used common commercial sulphate, which certainly contained a small amount of ferrous iron. The action of ferrous iron introduced a much debated subject. He did not consider that small quantities of ferrous iron were prejudicial.

Mr. WILLIAM THOMSON supposed that a wet season or damp surroundings was necessary for the development of this pest. He presumed that copper oxide must be soluble in water to some extent. Was that not so?

Mr. HENDRICK said the copper oxide as it rested on the potato leaves was in an insoluble state.

Mr. THOMSON said the combination of chlorophyll with copper made a colouring matter as permanent as indigo. The slightest trace of copper seemed to fix the dye well. One could not imagine an antiseptic effect being got from an insoluble substance, and it was worth while considering whether it would not be a good plan to spray these plants with an exceedingly minute quantity of sulphate of copper in solution.

THE CHAIRMAN inquired if ammoniacal solution had been used?

Mr. HENDRICK said he believed it had been tried, but an insoluble substance was required. The main point was to have something that would remain on the foliage, because the spores germinated on the leaf. This was prevented by the thin protective coating of the copper compound. If a soluble combination was put on the leaf it rapidly washed off or became absorbed by the tissues with injurious effects to the plant.

The CHAIRMAN: Have the tubers been examined for copper?

Mr. HENDRICK said, so far as he was aware, no copper had been found in the tubers. Where this mixture was used for fruit trees and sprayed directly on to the fruit—grapes, peaches, apples, and pears have been treated—copper was always found on the fruit rind, but so far as he was aware none had been found in the tissues of the fruit. Some American stations had experimented as to whether copper could be introduced into fruit, and so far as he could ascertain they had decided that there was no dangerous introduction of copper from the use of Bordeaux mixture. Small quantities of copper did not appear to be very poisonous.

Mr. THOMSON said copper was a natural constituent in the human body.

Mr. HENDRICK: And in small quantities in various animals. It had been found in the feathers of certain birds. It had also been detected in mangold-wurzel.

The CHAIRMAN: All were agreed that an infinitesimal quantity would do no harm, but what was the limit?

Mr. STEUART asked regarding the cost of the application?

Mr. HENDRICK: It varied from 10s. to 15s. per acre. This process was a prevention, not a cure. By the application of the mixture, spores were prevented from germinating on the leaf.

Mr. STEUART asked if the mixture prevented diseases associated with animal life?

Mr. HENDRICK: It had only been used for fungoid diseases. It prevented spore development.

The CHAIRMAN: It may do that by improving the health of the plant?

Mr. HENDRICK: No, apparently not.

Mr. ANDERSON said in moist weather the copper might be rendered soluble by the carbon dioxide in the rain-water.

Mr. HENDRICK did not think that solution was solely due to carbon dioxide. It did not do to apply the copper mixture without an excess of alkali. No doubt the acid juices of the plant were capable of rendering small quantities of copper soluble. The fungicidal action was probably due to slow solution.

Mr. THOMSON: It would be interesting to try the effect of minute quantities of copper or iron on pure cultures of the disease.

Mr. HENDRICK intended to do this, but had not yet had an opportunity.

THE STANDARD OF FLASH-POINT FOR MINERAL OIL.

BY D. R. STEUART.

(*This Journal*, 1896, page 173.)

DISCUSSION.

Mr. BEILBY was very much gratified to find that Mr. Steuart, had now, by careful experiments, answered a number of questions which were put on the last occasion on which the subject came before the Society. A notable point was the question of mass—the effects produced by larger quantities of oil dealt with in barrels and tanks and in larger vessels than ordinary Abel testers. Mr. Steuart showed that in these cases where the surface and the quantity of oil was increased the flash-point was directly lowered; thus the Abel test in its severe form was none too severe.

Mr. GRAY considered that Mr. Steuart had supplemented his former remarks by further investigations which were of very great importance. He personally found that in trying to explode oils in reservoirs of various sizes by means of the electric spark, he got results which were very

similar to Mr. Steuart's. The bulk of the oil and the explosibility of oil vapour and air in barrels and tanks was, he thought, a point which Mr. Steuart now rightly brought forward, because it was a weak point in the earlier paper. He deemed it advisable that the discussion should be adjourned in order to afford an opportunity of following out Mr. Steuart's experiments more closely.

Mr. BISHOP had experimented with a 9-inch Abel apparatus and obtained similar results to Mr. Steuart.

Meeting held Tuesday, April 7th, 1896.

Mr. D. R. STEUART opened the discussion by reading some supplementary remarks, of which the following is an extract:—

Mr. Spencer, in his recent report on Lamp Accidents and Experiments, takes the increase of temperature from burning between initial and final temperature of the oil. The initial temperature of the oil was always under the initial temperature of the chamber; and the room was heated during burning above ordinary summer evening temperatures, probably from many lamps being burned in the same room; but all is added together as if it were the ordinary heat of one lamp burning by itself. His figures prove that with ordinary lamps, 100° standard leaves a passable margin for safety. Persons who use large lamps or L.C.C. safety ones must use lighthouse oil of 150° flash, or treat the lamps with intelligence so that the explosive-mixture is not reached by a light. He thinks that "absolute security cannot be obtained by raising the flash-point," and no doubt he is right; yet, strange to say, he thinks that "almost absolute safety, no matter what kind of oil is used, is obtained if lamps and stoves are of right construction." He confesses frankly, however, that "if any practicable method can be found for preventing the use in lamps of all oil that is not perfectly safe, it may be desirable to adopt that course in preference to prohibiting the sale of unsafe lamps." That such a method and standard is practicable, and indeed quite easy, gentlemen here will no doubt be able to prove. I have been asked how much this would increase the price. I caused inquiries to be made of refinery managers and chemists in every producing district in America in 1893, and found that the cost at the works of ordinary export burning oil was generally 2 cents per gallon. Sometimes 3 cents was given as the cost, but that, I think, was high-flashing oil. But take 3 cents as cost. To convert ordinary export oil to 100 flash, it is required to take out of it at most 10 per cent. of naphtha and heavy oil. If these fetch as good price in the market as burning oil, then there is no extra cost at the refinery, for there is no extra expense in putting the naphtha into the naphtha tank instead of into the burning-oil tank. The most extreme case possible is if nothing at all could be got for the naphtha and heavy oil, in which case the cost of a gallon of burning oil would be increased about one-tenth. So that $\frac{1}{10}$ per cent., or $\frac{1}{4}$ d., extra at the refinery will far more than cover all extra cost. But if this increased cost does not reduce production, and there is no fear of that, the increased cost at the works in America or Russia does not necessarily mean increased price to the consumer. The price here does not depend on a little increase or decrease of cost at the refinery, but is altogether commanded by competition here. Let there be plenty of competing sources, American, Russian, Indian, and home, and the oil will be cheap; with plenty of competing sources, then, the addition of a farthing to the cost at the refinery will add nothing to the price to the consumer. No doubt if we reduce by one-tenth the yield of burning oil got from crude petroleum, if there was any decrease in production of crude oil, this would add to the price here considerably, but that is a very remote danger at the present time. The result of keeping the standard at its present low point will not have the effect of making oil cheap here; but, on the other hand, will cause the chance of oil being made much dearer.

Paraffin oil was freely used by the people of this country for nearly 10 years before the introduction of petroleum; so much so that when petroleum was introduced it was also called paraffin oil, a name already familiar to all the people. Young's patent was also used in America from 1852, and

the oil made under it. Rock oil gave its name to refined petroleum when it was introduced there. To show the extent of the paraffin oil trade in 1859, Mr. James Young bought 247,431 lamps from one maker alone, and in 1860 the same maker supplied him with 1,200 lamps per day. So that paraffin oil was to a large extent the oil of the common people before the introduction of petroleum.

There is one point on which Mr. Spencer and Dr. Chandler of New York are agreed, viz., that the safety of the people must be brought about by legislation. Attempting to educate them through the newspaper, county council instructions, &c., is found to be utterly valueless. The people most likely to have a lamp accident in London are not likely ever to have seen the L.C.C. instructions.

The CHAIRMAN asked what was the average of the standards in the United States?

Mr. STEWART said that there were 19 States that had no State law. Illinois with 155 tests had an inspection in every town and village on the requisition of five inhabitants. The tests varied from 105° to 150° fire test and from 100° flash-point to 120°. There were four States that had as low a test as England, but they used the low flash-point oil only for export:—

No State law or no State inspection.—Alabama, California, Colorado, Connecticut, Delaware, Idaho, Illinois, Kansas, Louisiana, Mississippi, Nevada, North Carolina, Oregon, South Carolina, Texas, Virginia, West Virginia, Washington, Wyoming (19 States). Some of these have efficient inspection in every city, and some even in every village. Illinois, for instance: 150° fire test; inspection in any town or village on requisition of five inhabitants.

110° Fire.—Maryland, Pennsylvania, Rhode Island, Vermont (4).

120° Fire.—Maine, Minnesota, New Hampshire, North Dakota, Wisconsin (5).

130° Fire.—Arkansas, Florida, Kentucky (3).

150° Fire.—Missouri, cities and towns of Illinois (1).

100° Flash.—Massachusetts, New Jersey (Elliot cup), New York (Elliot cup) (3).

105° Flash.—Iowa (Elliot) (1).

110° Flash.—Montana, South Dakota, Nebraska (Foster cup) (3).

120° Flash.—Georgia, Indiana, Michigan, Ohio (Foster cup), Tennessee (5).

Mr. WILLIAM THOMSON said that the subject had been brought before the Manchester Section some years ago. Mr. Stewart's present contribution was exceedingly opportune, because the matter was presently receiving serious consideration all over the country. The Manchester and Salford Sanitary Association had lately sent a requisition asking the Home Secretary to consider the question of raising the flash-point to 100° or over. He (Mr. Thomson) had been working at the subject for some time, and had an arrangement with the Manchester and Salford Sanitary Association whereby all the lamps which exploded were sent to him for examination, with a view to discover any peculiarities about them. There were a great many lamp accidents in Manchester and the neighbourhood. He had received a number of these lamps recently. The lamps which had apparently exploded *with a bang* had been all of one type, and that type was called the "Queen Anne burner." It was a burner made in America. It had a wick tube, at the side of which was a small tube which went between the flame and the inner portion of the receptacle for the oil, so that with low flash oils producing an explosive mixture inside the receptacle, the flame was put in the position best calculated to fire the vapours—over a touch-hole, as it were. He had called attention to that point in three distinct cases. In one case a woman was holding one of these lamps when some clothes were thrown down a neighbouring stair; this produced a sudden draught, the lamp exploded, and she was burned. In another case the lamp had been standing on the mantelpiece and suddenly exploded *with a bang*; and a third was standing on a kitchen table and suddenly exploded. These all had "Queen Anne burners." In another case with a lamp which had not a Queen Anne burner there was no evidence of it having exploded. A man and his wife were awakened by fire and smoke. The oil receptacle of the lamp had

broken. They had left the lamp turned down. He supposed that the flame had heated the brass work, the brass work had heated the glass oil-vessel, it had broken, and the whole thing had caught fire. He thought that would show that they ought to have metal receptacles for the oil, and not glass.

It was evident that Acts could not compel persons to procure properly constructed lamps. People with lamps could not be expected to discard one type and take to another. Consequently there was only one alternative—to make the oil safe. He hoped that a resolution would again be brought forward and be carried with unanimity again in the Society, and again placed before the Home Secretary.

Mr. J. STANLEY MUIR asked if Mr. Thomson had determined the flash-point of the oils which had caused the accidents?

Mr. THOMSON said he could not obtain the flash-points, as there was no oil left. The oils sold in England were 73°, 75° or 76°.

The CHAIRMAN said it was only by bringing forward from time to time such facts as had been brought before them by Mr. Stewart, proving beyond the possibility of dispute the dangers attending low flash-point as compared with high flash-point oils, that they could hope to induce those in authority to alter their views. There seemed, however, to be no possible doubt that the safety of oils was practically comparative—that was to say, comparative to the flash-point. The higher the flash-point the greater the safety. The temperature which was dangerous, was that at which the oil gave off vapour. To simplify matters he would be inclined to move as a resolution that, in the opinion of the meeting, oil of 73° flash-point was dangerous, and that the flash-point ought to be raised to 100° F., Abel test, with a view to public safety.

The motion, on being put to the meeting, was unanimously agreed to.

Meeting held on May 11th, 1896.

The PRESIDENT visited the Section on this occasion, and discussed various matters of interest with the local committee.

The following have been elected to fill the vacancies, and will take office in July next—*Chairman: Prof. C. F. Chandler. Committee: M. Aisberg, W. F. Foerst, A. H. Mason, W. Jay Schieffelin, and R. C. Schupphaus.*

*Meeting held at the College of Pharmacy,
Monday, April 26th, 1896.*

MR. A. H. MASON IN THE CHAIR.

THE CHLORINATION OF GOLD ORES.

BY J. DAWSON HAWKINS.

THE method of extraction of gold from its ores by means of chlorine is not a new one, although it has been only within recent years that its development has been such as to bring it into the front rank of metallurgical processes.

I will take the Cripple Creek ore as a special example, because my data on it are more numerous and extensive than on any other. The general chlorination treatment of all gold ores is, however, the same, and the statements made in this paper will be found to be of general application.

The crushing of the ore is the first consideration, and as a preliminary to that, the drying of it. The kind of drier to be used depends largely on the physical character of the ore to be treated. If it is hard, a revolving drier will answer, but if it is soft and wet, a shelf drier, such as the Stetefeldt, should certainly be used. In the latter the time of exposure of the ore to heat is under the control of the operator, and the ore is not taken out until dry, while in the former the progress of the ore is unimpeded, and at the end of a fixed time the discharge takes place regardless of the condition. A revolving drier also produces a large amount of dust. Taking all points into consideration, the shelf drier is the most satisfactory for general use.

The coarsest mesh, to which the ore can be crushed and still give satisfactory extraction, must be determined for each class of ore, and then the aim must be to produce a minimum of fines. The machinery must be chosen with this end in view. Rolls with hard steel shells will be found to be the most satisfactory,—with them ore can be crushed to 10 mesh and deliver only 4 per cent. of the material finer than 150 mesh.

In the Cripple Creek ores where the percentages of sulphur vary, it is found desirable to bed the ores before crushing, in order that the work of the mill be uniform. The ore is now ready for roasting. This roasting is a very important requisite in the preparation for the treatment by chlorine. All the sulphur, tellurium, antimony, arsenic, or anything capable of acting as a reducing agent, must be oxidized in order that there shall be no absorption of chlorine for other purposes than solution of the gold. The roasting of the ore accomplishes another important change which is of great importance in the treatment of the ore: it renders all particles porous, thus allowing of coarse crushing, and yet permits the chlorine being brought into contact with the particles of gold. This effect is due to the fact that the heating of the pieces of rock produces cracks all through them and makes channels for the dissemination of the chlorine solution. This fact can be easily demonstrated by taking a piece of rock and heating it in the muffle furnace and then holding with only one end in water. The porosity of the rock will be shown by the water rising in it as in a sponge. Even though the ore contained nothing to oxidize, it would be desirable to roast it in order to produce this effect. The operation of roasting must be a slow and careful one, for it is in the furnace that the real work of the chlorination mill must be done. If the work here is bad, addition of chemicals in the barrels will not overcome it. The time usually allowed for this is about three hours, and the heat at first must be light, gradually increasing to a bright cherry heat. The philosophy of this is that the gold existing in combination is found almost entirely with either sulphur, tellurium, arsenic, or other similar metalloid; and if the initial heat is sufficient to cause a fusion, the particles of gold will run into globules of matte and then resist all oxidation; but if the roasting is done slowly we accomplish a complete oxidation, and leave the metal in such condition that it is accessible to the chlorine solution.

It had previously been held to be true as regard tellurides of gold that roasting them produced loss. I have devoted especial attention to this, and have made very many careful investigations, and I can say authoritatively that this is not true. There is no loss of gold by volatilization in calcining. The loss is due to dust, and with proper arrangements for the prevention and the collection of dust, all the gold delivered to the furnace in the raw ore is turned out in the roasted product. And as regards the dust, in the arrangement of the chlorination mill proper arrangements for dust collection must be provided, as in no class of roasting furnace can its formation be prevented.

I wish to call especial attention to the fact that the roasting of gold ores must be a calcining one, and in no case may salt be added, because a loss as high as 30 per cent. may be produced by the formation of chloride of gold,

and no increased advantage will be attained in the preparation of the ore for chlorination.

There are, of course, many different types of furnace which are applicable to this work. In this, as in all roasting, the most perfect work can be done by the old-fashioned long-hearth reverberatory furnaces. But the cost of labour is so considerable with this type of furnace that it becomes necessary to use a mechanical furnace of some description. The mechanical furnaces can be described in three classes—the shelf furnace, the cylindrical furnace, and the flat-hearth of the reverberatory type. As it is necessary to leave but a very small percentage of sulphur in the roasted ore, the first-mentioned type, that of the shelf furnace, is not applicable to this work, because the ore cannot be roasted dead enough. Of the other two types, the White-Howell and the Brückner cylinder may be considered. A great objection, however, to these furnaces is the large amount of dust which is produced by them, and the consequent difficulties in the collection and treatment of it. The best form of furnace for this work is the reverberatory type, three of which are the Pierce Turret furnace, the Brown Horseshoe furnace, and the Ropp furnace. The Brown Horseshoe furnace is now in operation at the Golden Reward Mill, in Deadwood, South Dakota. As to their satisfaction with it, I cannot make any statement as it has been in operation only about three weeks. The Horseshoe furnace, however, has not given the best of satisfaction in the roasting of ores for smelting purposes. The criticism of this is on the method of operating the rabble arms in the furnace.

The Ropp furnace is a recent device. This also is in operation in only one place, the Selby Works, in San Francisco. An examination of it seems to suggest that it is very applicable to any class of work in which there is no sintering of the ore. It is a Pierce furnace straightened out with the slot in the middle of the hearth.

The Pierce furnace has been in use in this class of work in two chlorination mills—the Lawrence Gold Extraction Company and the El Paso Reduction Company, both of Cripple Creek District. From a great deal of personal experience with these furnaces at the El Paso Reduction Company, I can speak very strongly in favour of its use. It, of course, has defects, as have all forms of mechanical roasts, but the defects are not insuperable nor the cost of operation great.

The next step is the treatment of the ore in barrels. These are lead-lined steel cylinders, ordinarily 5 ft. in diameter and 9 ft. long, provided with a man-head and necessary valves to admit of the use of water pressure. The barrel is also provided with a filter inside. This may either be a sand filter, as described by Rothwell in the *Engineering and Mining Journal*, or asbestos cloth may be substituted for the sand. My own experience inclines me to favour the use of the asbestos as giving a better rate of filtration than the other. The barrel is charged with water to 50 per cent. of the amount of the ore treated, which, in this sized barrel, is a little over five tons. The sulphuric acid is then added to the amount of about 30 lb. to the ton of ore. The cold ore is then added, the bleaching powder placed on top of the ore, the man-head put on, the barrel started revolving and kept so for about three hours, when the revolution is stopped, the proper water connections made, and the gold liquor filtered from the ore under a pressure of between 20 to 40 lb. to the square inch. The number of revolutions per minute which it is most desirable that the barrel shall have, experience shows to be between four and five.

It had been the custom to revolve the barrels 8 to 12 revolutions per minute, but this causes a great deal of wear on the filter-cloth in the barrel and the chemical action is in no way increased.

When the gold exists as metallic particles of sensible size, the time of revolution of the barrel, and therefore of the action of the chlorine, must be increased, as the solution of these particles in the chlorine water is quite slow. In the Cripple Creek ores, to be absolutely sure of complete solution, it is necessary to allow this treatment to extend over four hours. In the chlorination mills in South Carolina small barrels, holding from one to two tons of ore, are used

and the filtration is effected in open filters on the outside. There are objections to this in the long time required for the washing of the ore, and in the injurious effect of the chlorine gas on the men. The difficulty in filtration could not have been so seriously felt in South Carolina mills because they treated only roasted concentrates, which, from their nature, must be free from slimes. It is, of course, possible to filter crude ore in open tanks, but the time required is a very important element in the working of the mill. The average time required at the works of the El Paso Reduction Company for filtering a charge in a barrel is between two hours and five minutes and two hours and fifteen minutes. In order that this average may be kept up, it is necessary that the men in charge of the barrel work should pay the closest attention to keeping the asbestos filter-cloth clear of slimes. If this is not properly attended to, after the first few charges in the barrel the time of filtration will increase to as high a point as 24 hours. There is, however, no necessity for anything of this kind taking place when proper precautions are taken with the cloth.

The average amount of water required in the chlorination barrels for each ton of ore treated is between 400 and 450 gallons. This figure is the total amount of water coming out of the mill as gold solution.

We now come to the precipitation and separation of the gold from the solution. There are a number of methods of accomplishing this, viz., treatment by sulphide of iron or copper, precipitation by ferrous sulphate, precipitation by carbon, and precipitation by hydrogen sulphide.

The following are the re-actions which take place—

The first two methods are, of course, practicable but not economical, nor is the resulting concentrate of sufficiently high grade; therefore I pass them with simple mention.

The precipitation of gold from its solutions by the use of ferrous sulphate is a method which has been largely used. The gold is thrown down as metallic gold in a very fine precipitate, and considerable difficulty attends its collection. Also in the presence of copper a very considerable quantity of the gold will remain in solution. As illustrative of this, I will cite an experiment I made on Cripple Creek ores. The solution was carefully precipitated with an excess of sulphate of iron and the precipitated gold carefully filtered off. The filtrate from this, which gave no further re-action with the iron solution, on being precipitated by hydrogen sulphide gas gave 30 per cent. of the gold originally in the solution. I will describe the apparatus and procedure in the precipitation of gold solution by means of carbon in the form of charcoal. The carbon filters employed are upright cylindrical vessels, about 4 ft. high and 30 in. in diameter, provided with an opening in the bottom for the escape of the waste liquor. The charcoal is crushed and the portion of it between 4 mesh and 10 mesh is collected and thoroughly water-soaked. It is then packed quite solidly into the cylindrical vessels. These are then filled with water, a heavy perforated lead plate placed on top of the charcoal, and the filter filled with water. They are now set in pairs, one above the other, and are ready for operation. The gold solution is heated to about 140 Fahr., and is then run on to the upper filter at a rate of from one to three gallons per minute. The waste liquor is allowed to run from the upper filter into the lower filter at the same rate of speed at which the liquor is fed, and the lower filter operated the same as the upper, allowing the waste liquor from the bottom of it to run outside. The gold is precipitated on the charcoal in a metallic form very finely divided, and is perfectly and definitely done unless the flow of liquor is made too rapid for the temperature. When the carbon-filter is sufficiently saturated with gold, it is washed, dried, and then the charcoal burned in open cast-iron pans. The heat is communicated by a fire from below. Although the reduction of the gold from the solution is perfect, the metal is not firmly enough held to the particles of charcoal to

resist being carried off by the current. Therefore, the properties of the charcoal as a filter must be depended on to prevent the escape of particles of metallic gold in suspension in the waste liquor. Some metallic gold, however, will be carried out into the lower filter, and there again the filter, as a filter, must be used to prevent the escape of these particles below. But in any case, taking all precautions, it is impossible to prevent the escape at the bottom of the lower filter of a small amount of gold in suspension. This amount the experience of the El Paso Reduction Company shows to be from five to ten cents per ton of ore treated.

Another objection to the use of carbon as a precipitant is in the burning of the carbon and the collection of the ash. The ash, although very high grade, consisting of about 70 per cent. gold, is a very fine powder, which cannot be handled without the production of dust, and therefore of a certain amount of loss. The gold is obtained from the ash by mixing it with proper amounts of sodium carbonate and borax glass and melting it down in a crucible. The metal produced is very fine, frequently going as high as 995. The precipitation of gold by means of hydrogen sulphide is the most satisfactory one in that it is absolutely definite and perfect in its work, and the cost of it is less than in any of the other methods. It is conducted as follows:—

The clear solution is run into the precipitating tank, and sulphurous acid, produced by burning sulphur in a current of air, is forced into the liquor. By this means all of the free chlorine in the gold liquor is reduced to the form of hydrochloric acid. The reaction which takes place is as follows:—

The sulphurous acid gas must not be allowed to act too long after reducing the free chlorine; it would reduce the gold to the metallic state as a very finely divided precipitate. The point at which the sulphurous acid must be shut off is distinctly indicated by the appearance of white fumes at the surface of the tank. The hydrogen sulphide gas is produced by the action of dilute sulphuric acid on iron matte in a closed lead-lined vessel, and the action is accelerated by a current of air forced in under pressure. This hydrogen sulphide gas is forced into the gold solution, thereby precipitating all of the gold as Au_2S_3 in the form of a flocculent dark brown precipitate. The precipitate is allowed to settle for a short time, then all the supernatant liquor is passed through a filter-press. The tank is then filled up with fresh gold solution and the operation repeated. When it is desired to thoroughly clean out the gold from the precipitating tank it is all run through the filter-press, where the gold sulphide collects as a mud. This is dried, roasted in muffle furnace, mixed with the proper amounts of sodium carbonate and borax glass, and melted down in a crucible. The gold produced in this way is not of as great fineness as that produced from the carbon ash, but the cost of the operation and the absolute definiteness of the precipitation and collection, joined with the fact that the value of the metal is not increased by its fineness, makes this no argument against it. This method of precipitation is pronounced by all those who have had experience in chlorination works as being the proper one for use.

I have thus far not referred to chlorination in open tanks, because the barrel process is the one most economical and easy of application. There are, however, several establishments where concentrates are chlorinated in open tanks. I will briefly outline the way in which this is done, but will not go into any detail of the work. The open tanks are lined with lead, and are provided with either a false bottom of wood or one of coarse sand. The ore is put into the vat and the chlorine gas forced into it from beneath the false bottom. When the gas makes its appearance at the top and has acted for a sufficient length of time, it is shut off, the tank filled with water, and the gold solution washed out. Another method for open tank chlorination is allowing a solution of chlorine to percolate through the ore from above. The solution is collected below in any ordinary manner. The precipitation in these cases is effected by one of the above-mentioned methods.

An ore to be particularly adapted to chlorination work should be free from silver, as there are but few cases in which the silver can be subsequently recovered by amalgamation

or by lixiviation with hyposulphite of soda. Some ores, however, permit of this. The Cripple Creek ore, although assaying too little in silver to consider saving it, has given as high as 77 per cent. metallic extraction. The gold, however, nearly always yields itself to the chlorine when the proper conditions have been complied with in the crushing mill and the roasting furnace.

Gold chlorination, however, is yet but an infant industry, but the advances which have been made in it within the last few years promise a future development which will bring it into the front rank of metallurgical processes.

DISCUSSION.

Dr. D. WOODMAN alluded to the use of bromine as a substitute for chlorine.

Dr. M. ALSBERG stated that in some of the Western States chlorine was produced electrolytically, liquefied, and then used for chlorination with apparent success.

Prof. L. STEVENS also detailed some of his experiences in the Venezuelan gold districts.

THE EFFECT OF COMPRESSION OF ILLUMINATING GAS UPON ITS CANDLE-POWER.

BY E. G. LOVE.

THERE are four systems at present in use for the artificial lighting of cars, namely, oil-lamps, carburetted air, compressed gas, and electricity. The first of these is the oldest, and admittedly the most unsatisfactory, while the electric light, on account of its cost, has not come into any extended use except on those lines which employ the electric current as a motive power. Carburetted air, that is, air mixed with the vapour of some volatile hydrocarbon, as gasoline, is used to some extent by several railroad companies, but it is open to many objections. The relative merits of the oil and compressed gas systems are very apparent to one who has occasion to travel up and down Manhattan Island after dark; and no one would hesitate to choose between the ample illumination on the cable roads, which is effected by compressed gas, and the rather poor twilight of the oil-lighted cars on the elevated roads.

The compression of illuminating gas for the lighting of cars, buoys, &c., has of late years become an important branch of the gas industry. The English and German engineers have been the pioneers in this direction, and to them is due the main credit for the present degree of perfection which this system has attained.

In the practical working of this system two methods have been followed. One consists in the compression of ordinary illuminating gas having a candle-power of from 16 to 28, while the other involves the manufacture of a special gas of from 40 to 60 candle-power, which, even after a certain loss by compression, furnishes a gas of far greater candle-power than that obtainable by the first method. With this latter the name of Pintsch will always be associated.

It is to be expected that the compression of an illuminating gas which owes its luminosity in part to benzol and other hydrocarbon vapours will result in the throwing down in a liquid form of more or less of this material, and thereby impoverishing the gas, the extent of this depending mainly upon the degree of its compression.

In practice it is customary to compress the gas in large cylinders to from 10 to 16 atmospheres (150 to 240 lb.), and afterward draw it off into smaller cylinders which are attached to the cars to be lighted. The pressure in these small cylinders seldom exceeds 10 to 12 atmospheres. In Germany we believe the law does not allow a railroad company to carry gas-cylinders beneath its cars charged to a greater pressure than 120 lb., or eight atmospheres.

It is apparent that by this plan of transferring from storage to service cylinders, any liquid products would be retained in the large or storage cylinder, and that gas from the small cylinders would presumably have about the same candle-power, whether tested when full or nearly empty. If, however, the gas is compressed in a

cylinder and afterwards used from the same cylinder, the probabilities are that as the pressure diminishes the gas will take up more or less of the liquids, and give a higher candle-power than when the gas is at the maximum pressure.

It is also evident that this difference in the quality of the gas will depend upon the quantity and nature of the condensed hydrocarbons in the cylinder; or, in other words, whether the original gas contained a large or a small quantity of those illuminants reducible to a liquid at the original pressure in the cylinder.

Several years ago Mr. C. E. Botley reported the results of a large number of experiments on the compression of coal-gas for the lighting of railroad carriages. His conclusion was that this gas lost little by compression, a gas of 16.32 candles, for example, when compressed to 13½ atmospheres (200 lb.) being reduced to 13.58 candle-power, or a loss of 16.79 per cent. He also found that the candle-power improved as the pressure was reduced, and that rich gases suffered more than poor ones by compression. In one case a coal-gas of originally 16.10 candles was reduced to 13.35 candles by compression to 13½ atmospheres, or a loss of 17 per cent. This would represent the value of such a gas when compressed in storage tanks and drawn off into small cylinders. The same gas was also tested at various pressures from 13½ atmospheres to the normal pressure. At 10½ atmospheres, or 155 lb., the candle-power was 14.56; at 6½ atmospheres, or 95 lb., it was 15.30; at 2½ atmospheres, 35 lb., the gas had regained its original candle-power of 16.10, and when the pressure became normal the value was 18.41 candles, a gain of 2.31 candles. With regard to the loss in volume it was found that a coal gas of 16.5 candles lost 1.16 per cent. in volume when compressed to 5 atmospheres, 2.54 per cent. at 9 atmospheres, and 7.47 per cent. at 13½ atmospheres.

His experience with oil-gas was that it lost from 23 to 25 per cent. in bulk and from 10 to 12 per cent. in candle-power by compression to 10 atmospheres. It is to be remarked, however, that for the reasons already stated there would be considerable variation in the loss in candle-power in the cases of samples made by different processes or under different conditions by any one process. It is stated on the authority of Pintsch that the loss of candle-power of oil-gas made from crude petroleum is 2.4 per cent. when the compression is carried to 5 atmospheres, 7.4 per cent. at 10 atmospheres, 16.3 per cent. at 15 atmospheres, and 21.5 per cent. at 20 atmospheres.

Not very long ago I had occasion to make a great many tests of railroad lamps using compressed gas, and in the course of the work an opportunity was afforded of making some observations on the loss which some of these gases suffered by compression. The object of this paper is to bring before you some of the results thus obtained, and I venture to do this more especially because in the majority of the tests water-gas was used, while the published results on this subject refer for the most part to coal-gas.

In the photometric work the burners used were Bray's Slit-Union No. 7, and Sugg's London Argand No. 1, the former better adapted to develop the candle-power of the richer gases, while the latter, which is the standard burner for coal-gas in London, is better suited to gases of 18 candles and less.

As the tests of the water-gases before compression were made with the flat-flame burner, it was necessary for the purpose of comparison to retain the flat-flame burner in testing the same gases after compression, although the Argand form was better adapted to develop the candle-power of the compressed, and thereby impoverished gas. The only tests made with a coal-gas were on a sample which was originally of about 16 candles, and which was compressed to 16 atmospheres or 240 lb. After compression the cylinder was placed on end and any liquid it contained was blown off through the valve. This gas was tested with the Argand burner, and when the cylinder pressure was 15 atmospheres gave 10.93 candles, at 7 atmospheres the candle-power was 11.07, and at 5 atmospheres it was 10.93. The loss was therefore nearly 32 per cent.—a figure considerably larger than that reported by Botley on gas of this candle-

power, although it must be remembered that in the present instance the pressure was nearly three atmospheres greater.

Of the many experiments made with water-gas I will mention only a few, as illustrating the results obtained under somewhat different conditions in the compression of the gas.

The first was with a sample of the gas as compressed by the Pennsylvania Railroad for use in the lighting of its cars. In this case the compression was carried to 17.5 atmospheres, or 262.5 lb., and the gas was removed from contact with any liquid products. The original candle-power of this gas was claimed to be 25, although I have reason to believe it was considerably less than this. The compressed gas had a specific gravity of 0.630, but no tests of its candle-power were made until the pressure in the cylinder had fallen to 6 atmospheres. From this point frequent tests were made until the pressure fell to 2.5 atmospheres, and the results were very uniform through this range of pressures, the average being 12.65 candles by the Argand burner. Another sample of water-gas was compressed under my direction to 11 atmospheres, but no attempt was made to remove the liquid from the cylinder. The uncompressed gas gave 18.34 candles by the Argand burner. The compressed gas had a specific gravity of 0.614, and gave the following photometric results:—

	Candles.	Loss per Cent.
At 9.5 atmospheres	12.39	32.4
" 6.0 "	14.29	29.1
" 2.5 "	15.72	14.3
" 1.75 "	17.51	4.5
" 1.0 "	18.21	0.7
" 0.5 "	18.28	0.3

These tests show that as the pressure diminished there was a steady improvement in the candle-power, until at last the value became the same as in the original gas.

A sample of water-gas from another source, which originally had a candle-power of 28 by the flat-flame burner, gave, after compression to 12 atmospheres, 13.20 candles at 10.5 atmospheres, and 15.92 candles at 6 atmospheres, with a specific gravity of 0.614. An effort was made to eliminate the effect of any liquid products by the use of two cylinders, much after the plan followed in the compression of gas commercially, but the results were not satisfactory. The method was to compress the gas in one cylinder to 16.5 atmospheres, then draw off half an atmosphere into the second cylinder, compress the first one again to 16.5, and so on until the second cylinder was full. In this way no gas entered the second cylinder which had not already been subjected to a pressure of 16 atmospheres. It is probable that the deposition of the hydrocarbons is a more or less gradual process, although in no case in which this plan was followed was I able to obtain any appreciable quantity of liquid from the second cylinder, possibly because the scale on which the experiment was made furnished no more liquid than would be retained by the rough interior of the cylinder.

To give a single case, a certain water-gas of 29.3 candle-power was compressed to 16 atmospheres. With this cylinder pressure the gas had a candle-power by the flat-flame burner of 16.09, and a specific gravity of 0.594, the candle-power increasing to 11.59 candles at 8 atmospheres, and 13.76 candles at 5 atmospheres.

Numerous other experiments might be cited much of the same nature as those already given, but I think enough has been said to show the very serious loss which water-gas suffers when compressed to the degree usual in car-lighting in this country.

In view of this fact, and the attendant circumstances that a much greater space is required for the quantity of this low-quality gas necessary to produce any given lighting, it is evident that the choice of such a gas in preference to an especially manufactured oil-gas of very high candle-power is a matter of very doubtful economy.

DISCUSSION.

Dr. D. Woodcock emphasized the influence of temperature in all analyses of gas.

The CHAIRMAN suggested the employment of liquefied acetylene for illuminating railway carriages.

Messrs. R. C. Woodcock, F. E. Dodge, and H. Schweitzer took part in the discussion.

A resolution of sympathy with Dr. C. F. Chandler (Chairman-elect) in his late severe illness, and of congratulation upon his recovery after a surgical operation rendered necessary thereby, was passed unanimously.

PATENTS.

Gases, Washing; Improvements in Apparatus for. P. F. Holmes, Huddersfield. Eng. Pat. 5113, Mar. 11, 1895.

A HORIZONTAL cylindrical casing is divided by vertical partitions into a number of compartments, every alternate one containing a brush or its equivalent, revolving on a horizontal shaft passing through the casing and preferably arranged slightly below the centre. The gases enter at one end, and pass from one compartment to the next through openings arranged near the centre of each dividing partition. The washing liquid enters at the opposite end, and flows to the end where the gases enter in such a manner that, after passing to any compartment, it is impossible for it to pass backwards and mix with the purer liquid therein. This may be done by providing the liquid outlet from each compartment containing a revolving brush, with a weir, from which the liquid overflows to the next compartment. By this arrangement the level of the liquid is gradually lowered as it passes through the apparatus. Other arrangements may be made, but in all cases the apparatus has compartments alternating between those containing the revolving brushes, &c., in which the liquid is comparatively still.—R. S.

Gases, Refrigeration of; Improvements relating to the Progressive. W. Hampson, Chester. Eng. Pat. 10,165, May 23, 1895.

THE gas to be liquefied is first freed from moisture, if it contain any, then compressed, and afterwards cooled. It is next led to the top of a casing and passes downwards through a number of small tubes, which are arranged in horizontal layers connected by curved ends, partitions nearly crossing

* Any of these specifications may be obtained by post by remitting 8d.—the price now fixed for all specifications, postage included—to Sir Henry Reade Lick, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C.

the casing and alternately fixed at opposite sides thereof, dividing off each horizontal set of tubes. At the bottom end, all the tubes lead to one orifice, which may be contracted at will. The gas thence passes into an expansion chamber, from which it ascends completely through the casing containing the tubes, its course being a zigzag, in consequence of the partitions already referred to, whereby it is kept in close contact with the small tubes carrying the incoming compressed gas. It is finally led away for use or sent back to the pumps. By this means an interchange of heat takes place, resulting in the gas which passes downwards becoming continuously colder, until at last it liquefies in the expansion chamber, and may be drawn off therefrom by a tube. The casing is provided with a double jacket, which is lightly filled with animal wool or cotton, and exhausted by means of a pump. The process is termed "self-intensive refrigeration of gas."

Evaporating Apparatus, Improvements in. J. Lee, New Ferry. Eng. Pat. 6491, March 29, 1895.

THE improvements consist in the application of one or more annular steam cylinders mounted on hollow trunnions on which they may be caused to rotate in the liquid contained in an evaporating chamber or pan, steam being introduced into the cylinder during rotation, through the trunnions. Within each annular cylinder a spiral conveyor is fitted so as to revolve in the opposite direction to that of the cylinder, in order to remove any deposit or incrustation from the inner surface of the cylinder and convey it to the end, where it can fall to the bottom of the pan or evaporating chamber. For the same purpose fixed scrapers are attached to the pan to remove incrustation from the outside periphery of the cylinder. A conveyor is also arranged at the bottom of the evaporating pan to convey the deposited crystals or substance to suitable openings in connection with apparatus where the crystals may be drained from the mother-liquor and removed, without interference with the evaporation.—O. H.

Evaporating Apparatus, Improvements in. H. H. Lake, London. From W. F. Jobbins and J. van Ruymbeke, Aurora, U.S.A. Eng. Pat. 4418, Feb. 27, 1896.

THE improvements more particularly relate to apparatus for evaporating waste soap lyes, where during evaporation, the liquor is liable to be mechanically carried over into the condenser. To prevent this, the patentee fixes a suitable number of superposed "dash plates" in the cylindrical evaporator above the level of the liquor, each dash plate being provided with a short pipe reaching nearly to the next "dash plate," and so arranged as to give a circuitous or zigzag course to the vapours. Return pipes are fitted over each plate to return the arrested liquor to the base of the evaporator. An intermediate vessel fitted in like manner may also be employed and placed between the evaporator and condenser if desired.—O. H.

Envelope or Covering for Use in Preserving Soluble Bodies, An Improved. A. Le Chatelier, Paris, France. Eng. Pat. 7192, April 8, 1895.

THIS invention has for its object the provision of an impervious envelope for preserving from dampness blocks of salt or other soluble bodies intended for export. To effect this, the covering of the envelope is formed of a resisting fabric which has been silicated or steeped in a solution of gelatin and then treated with alum. A coat of tar or pitch, or another impervious material, is then applied over this, and outside, a covering of coarse sacking or a sheet of waterproof paper is used.—H. S.

Coal and other Minerals, Washing; also applicable for Washing or Separating Chemicals, Vegetable and other Solid or Liquid Matter; Improvements in Apparatus and Appliances for. P. Muschamp, Barnsley, and S. Burridge, Sheffield. Eng. Pat. 8526, April 30, 1895.

THE apparatus consists of an inclined rocking trough, channel, or tube, having within it a concentrically arranged spiral conveyor. The coal, &c. is preferably fed into the trough, &c. near its lower end, while a stream of water is introduced near the upper end. The conveyor revolves in

a direction against the stream of water, whereby the lighter portions of the coal, &c. are carried by the water over the blades or through their open portions to the lowest end, where they are discharged through a hopper, while the heavier portions, shale and earthy matter, are carried upwards by the conveyor and discharged from the top end of the trough. The inclination of the trough is adjustable.

—R. S.

Lifting, Forcing, Circulating, or Heating Liquids, or for Propelling Air or other Gases, Improvements in Apparatus for. W. Allman, Handsworth, and J. Millward, Birmingham. Eng. Pat. 9593, May 15, 1895.

THIS invention relates to the construction of injectors and similar appliances for forcing gaseous liquids, and consists in constructing the passages at such angles that simple removal of a cap or plug will enable the whole of the nozzles to be inspected, and the passages freed from any obstruction, without breaking any pipe connections or joints.

—O. H.

Brewers' Refuse, Grains, and the like, Improvements in or relating to Apparatus for Drying. E. Makin, Manchester. Eng. Pat. 9835, May 18, 1895.

See under XVII., page 367.

Drying by Means of Furnace Gases and Air; Improvements in Apparatus for. F. D. Cummer, Cleveland, U.S.A. Eng. Pat. 16,052, Aug. 27, 1895.

THE material to be dried, as sulphate or carbonate of soda, potters' clay, salt, lime, malt fertilisers, corn, &c., is charged into an inclined rotary cylinder having a series of openings arranged spirally, and provided with hoods over the openings on the inside. The hoods are provided with fine wire gauze or the like over their inner ends, and with flaring shields, to prevent the passage of material out of the cylinders. The gases from a furnace mix with the air which enters through openings in the floor, and is heated, in some cases, by coiled pipes through which passes the exhaust steam from the engine which rotates the cylinder. The hot mixture of air and furnace gases then passes through openings in the furnace arch, and thence into the cylinder, after leaving which the gases may at once pass to the stack. They may also be drawn up a flue, and then forced by a blower to a cylinder arranged within a dust chamber. The dust which deposits is removed by a conveyor, and the products of combustion pass to the flues.

The cylinder is arranged so that on heating or cooling it can expand or contract.

The rotating cylinder is shown in one form as being provided with longitudinal lifters for raising the material to be dried to the top of the cylinder and tossing it down again.

—R. S.

Inking Rollers, Letterpress Printers', An Improved Composition for. W. Murray and J. Speirs, Glasgow. Eng. Pat. 22,449, Nov. 25, 1895.

THE composition contains, per cwt., 71 lb. 15 oz. of glycerin, 32 lb. of gelatin, 4 lb. of glucose, 4 lb. of glue, and 1 oz. of methylated spirits. The gelatin and glue are soaked in cold water for from one to two hours, the water is then decanted, and the gelatin and glue are left to soften for from 10 to 12 hours; they are then cut into pieces and melted in a glue boiler. The glucose, glycerin, and methylated spirits are then added, and when the ingredients have been thoroughly mixed and dissolved, the composition is allowed to season for four or six hours, and then cast into the form of rollers, the pin or stock for which should be heated for the better adhesion of the composition. The rollers made in this way retain a uniform elasticity, and do not shrink; they are not affected by change of temperature.

II.—FUEL, GAS, AND LIGHT.

Petroleum Lamps, Composition of the Gaseous Mixture formed. Flashing Points of Petroleum. H. Kast and F. Rose. Dingler's Polyt. J. 300, [4].

REVIEWING the standards of flashing point established in various lands, and the opinions expressed by a number of

chemists on the subject, the authors consider that the German standard, (21° C. Abel) is too low for safety. In order to test the security afforded by the existing standard, they carried out the experiments herein recorded, the results of which confirm that opinion, and they recommend the adoption of 40° C. Abel as being the minimum limit of flashing point consistent with safety with the class of lamps now in use, and in view of the difficulties in the way of rendering compulsory the employment of lamps of an absolutely safe character.

In the first place the experiments were directed to ascertaining the composition of the gaseous mixture formed above the surface of the oil in the lamp. To approximate as closely as possible to the ordinary conditions prevailing in practice, a 14-line "Kosmos" circular burner—without burton—was fitted on a glass receiver holding about 800 c.c. and provided with a tubulure at the top for the reception of a thermometer. The consumption of the oil was read off by the aid of a graduated scale attached to the receiver, outside. The collection of the gas for examination was effected by means of a metal tube soldered over the aperture existing at the base of the burner, and forming the connection between the interior of the receiver and the outside air, the gas being expelled by the introduction of a quantity of mercury into the receiver through a second tubulure at the bottom—a method which, in conjunction with the luting of a metal cap over the wick during the removal of the gas, effectually prevented any influx of air into the mixture.

Seven different kinds of petroleum were examined, viz., three American oils flashing at 22.5° , 23.5° , and 26.5° C. respectively; two Russian oils, one being Nobel's petroleum, 30.5° C. flashing point, and the other "Kaiser" oil, flashing at 50° C.; and two Scotch oils—Petroline of 54.5° , and lighthouse oil of 66.5° flashing point. Samples of the gas in the receiver were taken after 200, 400, 600, and 800 c.c. of the oil had been consumed—fresh oil being used in each case—and tested for explosibility as well as constitution, the temperature of the oil and vapour being also recorded.

The authors find that the inflammable constituents of the vapour consist solely of unsaturated hydrocarbons, all the saturated hydrocarbons capable of forming gas at lamp temperature having apparently been driven off in the distillation of the oil. The actual volume of the hydrocarbons present in the vapour is small, averaging between 1.4 and 1.8 per cent. in the case of American oils, 1.4 from Russian petroleum, 0.4 to 0.6 from the "Kaiser" oil, and 0.2 to 0.4 per cent. with the Scotch oils; or varying in inverse ratio to the flashing point. The absence of any inflammable gases other than those capable of absorption by bromine was proved by direct experiment. A small amount of carbon dioxide (about 0.3—0.4 per cent.) was also discovered and its presence ascertained to be due to oxidation, since pure air passed through glass wool moistened with petroleum caused a precipitate with barium oxide solution.

With regard to the temperature attained by the oil and vapour in the lamp, the highest points (34° and 37.5°) were reached by the American oil flashing at 22.5° , with a room temperature of 21° C. With a room temperature of 17° the American oils became heated to 27° — 32° , the "Kaiser" oil to 26° , and the Scotch oils to 27° — 29° , so that there is very little difference in their behaviour in this respect. When, however, the matter is viewed in relation to the flashing point, it becomes apparent that the heat attained by the American oil flashing at 22.5° is 11.5° above the flashing point, whereas, in the case of the oil of 26.5° flash, this overheating no longer occurs, and the higher flashing oils do not attain the temperature at which sufficient vapour to give a flash in the Abel tester is evolved.

The temperature of the vapour was found to exceed that of the oil by from 2.5° to 6.5° C., the average being about 4 — 5° C. Further examination showed that the upper layers of both vapour and oil reached somewhat higher temperatures than were attained by the middle and lower layers, the difference between the extremes being from 2° to 3° C. It was also ascertained that the percentage of hydrocarbons in the gaseous mixture was greatest in the upper layers, a circumstance probably referable to the

increased volatilisation of the oil adherent to the walls of the receiver adjacent to the burner.

A special series of tests with modern burners of large size and metal receivers showed that the oil is heated to a greater extent under these circumstances, the temperatures attained (room heat 21° C.) ranging from 32° (15-line "Sun" burner) to 42.5° (16-line "Central Vulcan" burner). With the great 30-line "Doppel Blitz" burner, giving a light of 77 candle-power (or three times that from the "Sun" burner), the temperature did not exceed 38.5° C.

The explosibility of the vapour was tested in a Hempel pipette by sparking from a powerful induction coil. A powerful explosion was occasioned by the vapour from the American oil flashing at 22.5° , particularly at 34° , or 11.5° above the flashing point, and when 800 c.c. of the oil had been consumed. Similarly, as regards this latter condition, an explosion of some violence occurred with the oil flashing at 26.5° , the temperature having reached 31° , but with the oil of 23.5° flash no explosion took place, although the percentage of hydrocarbons in the vapour amounted to 2.1, as compared with 1.8 per cent. in the other instances cited. This failure is considered to be probably due to some defect in the apparatus or performance of the test.

The authors are of opinion that the circumstances under which these experiments were made were less favourable for the production of explosions than the conditions actually obtaining in lamps, some reduction of temperature having ensued on the compression of the vapour in the pipette; and they believe that, where higher temperatures prevail in lamps, there is a probability that explosions of sufficient violence to shatter a glass receiver may occur. When radiation was checked by surrounding the lamp with a shield, the temperature (that of the room being 21°) of the oil rose to 38° and that of the vapour to 41° , the amount of hydrocarbons therein increasing concurrently to 2.2 per cent. Sparking with the induction coil produced a powerful explosion.

In order to ascertain the lamp temperature necessary with different oils, for the production of an explosion, a lamp receiver filled with oil was heated on a water-bath, and by the aid of a ring burner over the mouth of the receiver, the mouth being corked, but provision made for access of air, and also for replenishing the oil as fast as it would under ordinary circumstances be consumed. The American oil flashing at 24° gave an inflammable mixture of vapour (containing 1.6 per cent. of hydrocarbons) when the upper layer of the oil indicated 30° — 35° , and an explosive one at 35° — 40° (2.2 per cent. of hydrocarbons). With the oil flashing at 26.5° the temperature reached 35° — 40° before the gas (1.5 per cent. of hydrocarbons) ignited, and 45° to 50° (hydrocarbon percentage 2.0) for the explosion. In the case of Nobel's petroleum (30.5° flash) the results were similar, save that the explosion temperature lay between 50° and 55° , but the Kaiser oil gave off only 1 per cent. of hydrocarbons in the gas, even when heated to 95° , and neither ignition nor explosion could be induced.

The fact that lamp explosions are less frequent than might be supposed, is considered due to the gradual escape of the vapours and their dilution by the air current to below the explosion limit. Attempts made to ignite the vapour by means of burning fragments of wick dropped over the aperture in the base of the burner, or by lighting the accumulated scrapings lying there, failed, although when a light was inserted into the receiver an explosive ignition was produced. On the other hand, explosions were easily caused, both with the American and Russian petroleum, at 28° to 32° , when wicks too small to fill the duct were used, the intensity being in inverse proportion to the height of the flashing point. The explosion began by a flickering of the flame, succeeded by several slight explosions in the duct, and finally extended to the vapour in the receiver, the shock extinguishing the flame. It is however, admitted that authentic lamp explosions are of comparatively rare occurrence, although accidents resulting from the careless handling of oil are frequent enough. The German statistics cited (1888 to 1890) show that the fires occasioned by petroleum, amount to an average of only 1.53 per cent. of the total fires from all causes, and in those for London,

90 out of 448 petroleum fires in 1894 were ascribed to lamp explosions, the remaining 337 being occasioned by the overturning of lamps.—C. S.

Manganese Carbide. H. Moissan. *Comptes rend.* 1896, 122, 421.

This compound, Mn_3C , made by Troost and Hautefeuille in the wind furnace, is now prepared by heating a mixture of Mn_2O_3 and sugar charcoal in a carbon tube closed at one end, placed in the electric furnace. With a current of 350 amperes and 50 volts the operation lasts five minutes, with 900 amperes and 50 volts the reduction is almost instantaneous.

The carbide has the density 6.89; fluorine attacks it in the cold, producing a violet-coloured fluoride; the action of chlorine commences at a somewhat high temperature, but as soon as the incandescence begins it continues unaided. Gently heated, it burns in oxygen, nitrous and nitric oxides. Ammonia reacts at a dull red heat with production of a nitride and evolution of hydrogen; dilute hydrochloric acid produces liquid hydrocarbons; gaseous hydrochloric acid below a red heat gives manganous chloride and hydrogen mixed with a small quantity of hydrocarbons. The action of water on the carbide is to produce a mixture of equal volumes of methane and hydrogen only, and no acetylene or ethylene—

Flames, On the Temperature of Certain. W. N. Hartley. *Proc. Chem. Soc.* 1896, [164], 98.

THE author measured the temperature of flames by means of gold-leaf and with fine wires of platinum $\frac{1}{10000}$ in. diameter, such as were drawn by Wollaston and used by Faraday, also with pure platinum wire $\frac{1}{10000}$ in. thick. He furnishes evidence of the high temperature of a candle flame, not only from the melting of gold and of platinum in the flame, but by an examination of the spectrum to be seen in the mantle. Experiments made with platinum wires heated in a bat's-wing gas flame are described, which proved that the carbon does not lower the melting point of the platinum, at any rate in any appreciable degree. A small carbon monoxide flame melts platinum wire $\frac{1}{10000}$ in. in thickness, and a cyanogen flame was shown to be intensely hot, for it melted such wire with extreme ease. The author believes that his experiments have dissipated the doubt that was cast on Prof. Smithells' statement of the high temperature of the mantle of the Bunsen flame, and confirm his own estimate of the high temperature of the Bessemer flame (this Journal, 1895, 1037).

Spirit, Incandescent, and Petroleum Lamp: A Comparison of the Illuminating Powers of the. Hayduck. *Zeits. für Spiritusind.* 1896, 80—81.

THE spirit incandescent-lamp consists of three parts: the vaporiser, the burner, and the mantle. The latter is similar to those in use with gas-burners. A spirit (alcohol) of fair strength must be used, which is vaporised and then burnt. By the flame thus produced the mantle is raised to incandescence. The author has compared the cost of lighting with this lamp and with a petroleum lamp producing the same amount of light, and finds that it is from 12 to 33 per cent. cheaper.—A. L. S.

Acetylene, Commercial Value of. Engineer, 1896, 81, 417. ONE kilo. of calcium carbide and 500 grms. of water will produce 300 litres of acetylene gas, and this, it is stated, will provide a light equal to 15 ordinary gas jets for 6 hours. The burner used has a smaller orifice than an ordinary burner. In France, acetylene is now produced on something like a commercial scale, and its cost can therefore be compared with that of ordinary gas. The price of coal gas per carcel hour is one centime, while acetylene gas costs 3.2 centimes; but acetylene being much more powerful, the cost works out in practice to about the same as that of coal gas.

Acetylene gives off very little heat in burning, and thus cannot well be employed for heating purposes and for driving motors.

Acetylene producers are now being supplied by a company in Paris at the price of 6*l.*; they have a capacity of 1 kilo. of calcium carbide, and will provide a light equal to 10 ordinary gas burners for 6 hours.

A large number of works are now being built on the Continent for producing calcium carbide, and when in full operation, the present price of 70 centimes to 1 franc per kilo. of carbide is expected to fall to 50 centimes. It is possible now to obtain large supplies of carbide at a lower price than that quoted, but it is of very inferior quality, producing only 150 litres of acetylene per kilo. instead of 300 litres.—A. S.

Light-Standard, Acetylene. J. Violle. *Comptes rend.* 122, (1896), 79—80.

THE acetylene flows into a conical chamber, carrying with it the air necessary for its combustion, then enters a narrow tube in which the mixture takes place, and issues through a steatite burner, which gives a large flat flame. The whole of the flame may be employed, or a sharply limited portion of it. In the standard pattern the flame is enclosed in a kind of box, one face of which carries an iris diaphragm so constructed that any required candle power can be used and read off. Under a pressure of 0.3 m. the whole flame has a candle-power somewhat greater than 100, the amount of acetylene consumed being 58 litres per hour. Thus the illuminating power of acetylene is more than 20 times that of coal gas burned in a Benger burner (giving 1 carcel = 9.6 candles per 105 litres), and at least six times that of coal gas in an Auer burner (giving 1 carcel per 30 litres). The spectro-photometer shows that throughout the spectrum from C to F the light given by the acetylene differs but slightly from that emitted by fused platinum, with reference to which the absolute unit is defined.—D. E. J.

Coal in Kent. Ironmonger, May 2, 1896, 171.

AFTER some years of patient investigation, the making of various trials, and the expenditure of a good deal of money, it has been established that coal exists in workable seams in the vicinity of Dover. The seams are deep, and some of them are not very thick, but they are said to be worth working, and accordingly they are to be developed forthwith. The Kent Coalfields Syndicate has been formed to work the pits, has bought some 575 acres of land with the minerals thereunder, and has arranged for the sinking of two pits, capable of raising some 2,500 tons of coal daily. The seams are stated to be as follows:—

1,229 ft. deep.....	2-ft. seam.
1,279 ft. "	2-ft. " "
1,456 ft. "	2-ft. 6-in. seam.
1,570 ft. "	2-ft. 3-in. " "
1,763 ft. "	2-ft. 9-in. " "
1,831 ft. "	1-ft. 8-in. " "
2,177 ft. "	4-ft. seam.

Of these, two are said to yield good, bright house-coal, and the thick seam a good bituminous quality. It is estimated by the syndicate that the coal can be put into railway trucks at 6*s.* to 6*s.* 6*d.* per ton, and the full output can be readily absorbed within an area from the pits covered by a 2*s.* 6*d.* per ton railway rate. At present good house or gas coal realises 14*s.* per ton and upwards, even when seaborne, so that if the figures are correct, there should be good profit on the working of the pits. The opening of collieries in Kent will not improve the district from a tourist or artistic point of view, but that will not count for much if the mines can be run at a profit. It would be odd if the whirligig of time, as thus evinced, should lead to a revival of the long disused Sussex iron trade. If there is coal in the locality, even that would not be impossible.

PATENTS.

Electrodes [for Heating Purposes], Improvements in the Construction of. A. B. Woakes, London. Eng. Pat. 23,637, Dec. 6, 1894.

THE inventor has worked out some calculations relative to the action and efficiency of electricity as a heating, cooking, and sterilising agent. He deals with his subject under

such heads as Electrodes; Circulation of Water in Electrodes; Resistance of Water Diminishes with Increase of Heat; Glass Water Boiler; Action on Impurities in Water; Latent Heat of Electrolysis; Efficiency of Water Boilers; Calculations for Electric Egg-Boiler, &c. His claims are for the construction of platinum-foil electrodes stiffened or supported by vitreous enamel, or toughened glass, or plates of china; supporting sheets of platinum-foil between perforated china plates, or plates of celluloid or ebonite; and for other apparatus described in drawings, of which there are seven sheets. Eng. Pats. 259 of 1892 and 11,749 of 1893 are referred to.—J. C. R.

Vapour from Oils and Hydrocarbons [Oil - Vapour Lamps]. Improvements in and connected with Apparatus for Automatically Producing and Simultaneously Burning. R. A. Poirimol, Paris. Eng. Pat. 6245, March 26, 1895.

The oil is contained in an annular receiver surrounding the chimney, and is fed by capillary attraction through tubes filled with a suitable spongy material into a vaporising chamber, the latter being situated immediately over the flame. The vapour issuing from it under pressure, mixes with air automatically drawn into the burner. The latter is of ring-form, the flame passing outwards and upwards through a central chimney.—R. B. P.

Gas-Burners, Incandescent; Improvements in. A. Besson, Paris. Eng. Pat. 6690, April 1, 1895.

The Bunsen burner has adjustable gas- and air-inlets, and at its upper end is provided with a combustion chamber containing an inverted cone which deflects the mixture of air and gas outwards. The combustion chamber also contains a strip of sheet metal, bent into a star-shape, which acts as a recuperator. Fitting over the outside of the combustion chamber is a collar with two lugs on it, into which fit the legs of a U-shaped rod, supporting the mantle. —R. B. P.

Gas-Burners, Incandescent; Improvements in. D. W. Sugg, London, London. Eng. Pat. 6870, April 3, 1895.

The essential features of this burner are (1) the use of an open-topped mantle, (2) the supply of an independent draught of air to the Bunsen flame, (3) an automatic disc valve in conjunction with the pilot flame. (1) and (2) promote more nearly perfect combustion, thereby preventing the deposition of carbon on the upper part of the mantle, and also prevent the flame being deflected through the mantle on to the glass chimney and cracking it.

The object of (3) is to enable a single tap to be used with a pilot flame.

The tap is provided with a second, removable stop-pin, which, when in position, prevents the tap being quite closed, so that a quantity of gas sufficient for the pilot flame, but insufficient to lift the disc valve, through which the main flame of the burner is fed, is allowed to pass.—R. B. P.

Gas Apparatus [Incandescent] for obtaining Light and Heat, Improvements in. J. W. Mackenzie, London. From F. de Mare, Paris. Eng. Pat. 7481, April 11, 1895.

A BUNSEN burner giving a flat vertical flame in which is suspended a hanging fringe of refractory threads capable of incandescing.—R. B. P.

Gas Lamps, Incandescent; Mantles, Improvements in the Manufacture of, or Luminous Bodies for, and in Compounds for Use in such Manufacture. H. Reeser, Amsterdam, Netherlands. Eng. Pat. 10,129, May 22, 1895.

The following ingredients are taken in about the proportions named: 3 to 4 parts by weight of boron nitride, 25 to 30 of thallium nitrate, 2 to 3 of titanium nitrate, 2 to 3 of samarium nitrate, 2 to 3 of neodymium nitrate, and 3 to 4 parts of magnesium nitrate. The nitrates are dissolved together in water to form a concentrated solution and the boron nitride, dissolved in heated nitric acid, is, after

filtration, added thereto. The usual cotton fabric is then used for dipping, drying, and igniting in the ordinary way. A more intense light is said to be obtained with the mixture of oxides so produced.—A. W.

Mantles, Improvements in, for Incandescent Light. S. H. Crocker, London. Eng. Pat. 19,202, Oct. 12, 1895.

To the nitrate or other salt of thorium hitherto used is added about 1 or 2 per cent. of the corresponding salt of ytterbium, scandium, or thulium, or a mixture of two or more of these substances. The mantle is made in the usual way, and is stated to be flexible and capable of giving an improved light.—A. W.

Mantles (Glow Bodies) for Incandescent Gas Lighting. C. Kortwich, Berlin, Germany. Eng. Pat. 2000, Jan. 28, 1896.

Boron, arsenic, or antimony, or any salt thereof in small quantity, is included in the mixture for producing the mantle, which is thus rendered less liable to fracture, by being more cohesive and less sensitive to atmospheric dust. The following mixture is given as an example, the chloride of antimony therein forming with the earthy bases, on ignition, a small quantity of antimonate of high basicity, which renders the mantle more cohesive without lowering its melting point.—Thorium nitrate, 22.25 parts; lanthanum nitrate, 2.75; cerium nitrate, 1.50; yttrium nitrate, 0.35; chloride of antimony, 0.75; zircon nitrate, 2.00; pyrotartaric acid, 2.00; and water, 70.00 parts.—A. W.

Lamp, An Improved Incandescent Oil- or Spirit- H. Hempel, Berlin, Germany. Eng. Pat. 2576, Feb. 4, 1896.

This patent is for a lamp in which the spirit is burnt as such in direct contact with a mantle instead of being previously gasified. The wick is a circular one, and round its upper end is a metal ring or collar on which the mantle mainly rests. Inside the mantle is a perforated cylinder, closed at the top, and of smaller diameter than the wick, through which the air is supplied. The device is so arranged that in lifting the chimney and upper part of the burner to light the wick, the mantle with the ring on which it rests is also raised. The air enters through the perforations at right angles to the inside of the flame and forces it into the mantle, which is thereby rendered luminous.—A. W.

Hydrocarbons, Heavy; Improvements in Apparatus for Treating by Means of Heat, especially applicable for Distillation and the Manufacture of Oil Gas. S. Pitt, Sutton, Surrey. From La Société Internationale des Procédés Adolphe Seigle of Levallois Perret, Seine, France. Eng. Pat. 23,235, Dec. 4, 1895.

The apparatus is characterised:—(1.) "By the use of a bath of lead heated in any suitable manner, its object being to maintain the apparatus at as constant a temperature as possible." (2.) "By the separation of the apparatus into elements of two kinds, namely, elements vaporising by circulation and elements for treating, by means of heat, the vapours generated by the first." (3.) "By a specially constructed apparatus, having for its object both to permit the unequally liquefiable vapours to be collected at different levels, to separate by condensation the vapours not yet sufficiently heated, and to progressively heat the heavy hydrocarbon to be treated, which does not enter the vaporising elements, and the apparatus for treatment with heat until it (the heavy hydrocarbon) has fallen in thin streams in a contrary direction to the ascending vapours and has been charged with those vapours, which should be returned to the heating apparatus." (4.) "By an automatic arrangement for regulating the temperature of the metallic bath by means of a pyrometer acting upon the delivery mechanism of the gasifier of the heavy hydrocarbons serving as fuel." The heating elements are grouped in batteries, that is to say, the vapours are led out separately from them into a single collector, whilst the vaporising elements, each of which is fed separately, are grouped in series, the heavy hydrocarbon being made to successively traverse the vaporisers before

entering the apparatus for treatment by heat. The heating elements are filled with such material as iron chips or pumice stone. In its passage the hydrocarbon deposits tar in the heating elements, which must be removed from time to time.—D. B.

Gases, Washing; Improvements in Apparatus for. P. F. Holmes, Huddersfield. Eng. Pat. 5113, March 11, 1895.

See under 1, page 340.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Petroleum Deposit in the Kouban Province of the Caucasus. H. H. Nidenführ. Chem. Zeit. 1896, 20, 69–70.

THE Kouban petroleum zone, which has hitherto, it is said, suffered neglect, is about 220 versts in length, extending from the Black Sea, near Anapa, in a northerly direction to the German colony Michael'sfeld, and from there to the White River and to Maikop. At many points the oil is brought to the surface by the mountain streams, especially in the neighbourhood of the Kouban River and its tributaries. In spite of the extent of this district, its industrial importance is limited to the Ilin district, which is seven versts from Ilinskaja on the Vladikavkas Railway. The naphtha-bearing strata consist of soft, gritty, argillaceous deposits of the lower tertiary period, and of the ejections of the mud volcanoes, but the distribution of the petroleum in them is very irregular. The oil varies in colour from light green to colourless; its sp. gr. is 0.755–0.815, and it yields 80 per cent. of illuminating oil. In the Ilin district, which is worked by a French company, there were 100 derricks in 1893. The uppermost oil-bearing stratum consists of magnesians limestone, containing petroleum, and water tainted with hydrogen sulphide. The specific gravity of the oil varies between 0.920 and 0.990, and the thickness of the oil-bearing dolomite is 60–80 ft., the upper portion being richest in oil. Beneath the dolomite are two more zones bearing light oil, both consisting of sandstone, the lower one being of considerable magnitude. The heavy oil of the upper strata is reached at a depth of 300–350 ft., and yields on distillation about 13–17 per cent. of inferior illuminating oil. Petroleum is also found in the valley of the Kudako River, 17 versts from Krimskaja. A well which in 1886 was sunk here to a depth of 120 ft., yielded at first 1,500 poods daily, and on increasing the depth to 183 ft., this rose to 3,000 poods. The depth was subsequently increased to 225 ft., and during two months the daily yield then rose to 5,000 poods of oil of sp. gr. 0.865. The seven wells which were working in 1890 only yielded 38,568 poods of crude oil in the year. The Kulako petroleum gives 10–12 per cent. of benzine, 6 per cent. of gasoline, and 33–37.5 per cent. of illuminating oil.

—A. K. M.

Galician Petroleum in Germany. Board of Trade Journal, May 1896, 597.

Kuklow's states that Galician oil has now begun to compete with the American product in Germany. (See this Journal, 1895, 698.) For the first time the export of refined petroleum from Austria-Hungary to Germany has been made possible by the decline in the price of the Galician crude oil, caused by the greatly increased production in that country. The price of Galician crude was formerly 4 florins, but since the opening up of the great wells at Schodnica it has fallen below 2 florins. This made it possible to produce refined petroleum at a figure which allowed an export to Germany. In fact, several refineries, especially that at Pardubitz, Bohemia, have commenced to compete with the American petroleum in the German market, and large quantities of refined oil have been exported already to Germany, mostly to Bavaria and Saxony. The Austrian railroads are assisting the refiners in their export trade by reducing the freight rates. Since 1st November a specially reduced freight tariff for refined petroleum and crude benzine has been in force for the export to Bavaria. The export of crude oil to Germany is

impossible at present, because the German import duty is the same on crude as on refined petroleum, namely, 6 marks (6s.). But as in Germany the desire becomes steadily stronger to supply the home demand by home production, that is refining, and to renounce the American oil, it may be possible that the import duty on crude will be reduced so as to allow the export of Austrian (Galician) crude oil to Germany.

Petroleum, Valuation of. K. Charitschkow. Jour. Russ. Phys. Chem. Ges. 1895, 1, 196.

POZILITZIN and Bernstein have stated that a sample of petroleum from Tschengelek contains 43.8 per cent. of kerosene. This statement is apparently founded on observations of the quantity of oil distilling between 150° and 300° C. The author contends that an upper limit of 270° C. should be adopted, and he further points out that a single distillation is inadequate, it being necessary to collect first the fraction passing over between 140° and 270° C., and then to distil this fraction between 150° and 270° C. Concordance between laboratory experiments and manufacturing results can only be obtained by conducting the distillation in a current of superheated steam or under diminished pressure. It is generally true that all varieties of petroleum begin to decompose between 250° and 275° C., and there is no reason to suppose that the particular sample now in question is an exception to this rule.—B. B.

Petroleum, Effect of Sunlight on the Oil, and on its Capacity for absorbing Air. R. A. Ostrejko. Trudy bak. otd. imp. russk. techn. obschtsch. 10, [4], 19.

THE experience of the author with regard to the acid process in refining, leads him to conclusions contrary to those expressed by Charitschkow (this Journal, 1896, 24), oil refined in this manner having a more agreeable odour, and being less inclined to become cloudy, absorb air, and oxidise, than when the alkali method alone is practised. This is due to the removal by the acid of the substances from which the petroleum acids are formed. More exact experiments show that well-refined oil on exposure to the air becomes at first lighter in colour, up to a certain limit, after which point it begins to darken again, the extent of the initial transformation being in one sample of Russian oil examined, 18 mm. in $\frac{3}{4}$ hour (measured by Stammer's colorimeter). Further tests were made with Baku oils examined at intervals, and stored in the dark, when the colour (initially 12 mm.) registered 152 mm. The next day, the register was 115 mm., and receded to 106 mm. in another 24 hours, although protected from all light. Air was found to be absorbed throughout the whole period. Sun-bleaching is therefore an unsuitable process for Baku oils.

The influence of various shades of glass on the alteration of the colour of the oil was also studied. Starting with an initial colour degree of 115 mm. Stammer, it was found that the maximum decoloration was reached between 3 and 9 hours, after which darkening set in, with the following comparative results as to the colour at the end of 43 days' exposure:—

	Deep Orange.	Orange Yellow.	Green.
Colour in mm. Stammer	Mm. 75	Mm. 26	Mm. 21
Acidity	0.06	0.33	0.45
	Pale Green.	Blue.	Colourless Glass.
Colour in mm. Stammer	Mm. 9	Mm. 7	Mm. 6
Acidity	1.71	2.7	3.6

the initial acidity having been in each case 0.03.

With regard to the absorption of air by crude and refined petroleum (this Journal, 1896, 26), oil of sp. gr. 0.855 at 28° C. from a well at Balakhany, absorbed air

rapidly at first, and in 10 days, the whole of the air in the eudiometer tube employed for the experiments. The decreased absorption in the later stages being probably due to the presence of gaseous hydrocarbons or water vapour in the testing vessel, the experiment was repeated with oil previously heated to 110° and filtered, as well as with cylinder oil distillate, machine oil distillate, spindle oil distillate, and residuum, with the result that in the case of the first-named oil, the time required for absorption was reduced to 4 days, the spindle oil required 10 days, and the remaining qualities much longer.—C. S.

Benzene, Preparation of, from Petroleum and Residuum.

A. Nikoforow. Chem. Zeit. 20, 8—9.

In this process the material employed is twice subjected to decomposition, the first time at about 525°—550° in cast-iron retorts, under ordinary conditions of pressure. The heating arrangement is such that the receiver is kept at about 200°, so that only the distillates boiling above that temperature are collected there, the lighter fractions (sp. gr. 0.800—0.810) being condensed in a worm and redistilled, and the uncondensed gases passing into a gasometer. In the second distillation, which is carried on in an upright still with small dephlegmator, the fractions are divided into those boiling at 100°, 130°, 160°, 180°, and 200°, each of which is again decomposed in retorts similar to those employed in the Pintsch process for making oil gas, the lightest at about 700° and the heaviest at 1,200°, under a pressure of 2 atmospheres. The temperature in the receiver is maintained at 150°—200°, so that only the heavier portions of the aromatic tar are retained. The lighter distillates are condensed, and contain 30 to 35 per cent. of benzene. In order to obtain fractions with a smaller range of boiling point, these are united with the contents of the receiver and redistilled. The resulting fraction passing over at 120° constitutes the crude benzene, whilst those between 160° and 200° are returned to the second decomposing still, and the fractions of higher boiling point are employed for the production of naphthalene, anthracene, &c. The heavy distillates from the initial stage can also be re-decomposed for benzene, but require a much higher temperature than the lighter fractions, and yield less benzene, the production of carbon being greater. The total yield of benzene obtainable by the process is about 12 per cent. of the weight of the original oil.—C. S.

Petroleum and Bitumen, Preparation of Solid Resins and Aromatic Hydrocarbons from. A. W. Adiasiewitsch. Zap. imp. russk. techn. obschtsch. 29, 93.

Thick resins have been prepared from lubricating oil residuum in Baku for the English market since 1891, by driving off the more volatile portion of the residuum at about 400°, either by direct fire or superheated steam. This method yielded a large percentage of coke, and quickly corroded the plant, besides giving rather unsatisfactory products, those from the steam process containing much paraffin and being difficult to refine, whilst dry distillation resulted in readily decomposable products of no practical value.

The yield being low and the product little adapted to replace asphalt, by reason of its deficient elasticity and viscosity, the author has elaborated a process which is carried out at between 150° and 200° in an ordinary still by means of a blast of de-oxygenated air with the simultaneous discharge of electricity. Treated in this manner, a residuum of sp. gr. 0.930, acquired in 3 hours a density of 1, with an increased flashing point, and on continuing the process for 10 hours the product, amounting to 75 per cent., had a specific gravity of 1.06. This and the intermediate products obtained by curtailing the process, are very viscid and completely soluble in petroleum spirit and turpentine.

The absence of distillation products indicates that the thickening of the oil must be due to chemical change. When treated in the usual manner for the preparation of aromatic hydrocarbons, a larger proportion of anthracene and benzene is obtained from this resin than from ordinary heavy-oil residuum, which points to the elimination of hydrogen during the formation of the resin.

Experimenting with a natural asphalt consisting of 83 per cent. of sand and 17 per cent. of bitumen soluble in carbon bisulphide, it was found that the only methods of treatment whereby the natural elasticity of the bitumen remained unimpaired, were, distilling with superheated steam and the de-oxygenated air blast. The specific gravity of the distillates increased from 0.936 to 0.972, the consistency varying in proportion. When refined they corresponded to the Baku lubricating oils. The residue, amounting to 50—75 per cent., yielded products varying with the duration of the treatment, 12 hours' distillation leaving a fluid tar, and 20 hours a solid residue.

With the new air process from 4 to 10 hours is sufficient. Only half the usual amount of fuel is necessary; there is no distillate, the evolved gases being permanent and incombustible, but the yield of resinous products amounts to 85—95 per cent. and the resins retain their natural viscosity, the more solid bodies being elastic. There are four products, exhibiting the following characteristics:—

	Yield.		Specific Gravity.	Flashing Point.	Burning Point.
	Steam Distillation.	New Process.			
No. 1. Fluid	80	95	1.005	202°	295°
No. 2. Soft	70	90	1.02	227	256
No. 3. Semi-solid.	60	85	1.04	254	271
No. 4. Solid.	50	80	1.06	276	302

All are soluble in petroleum distillates, ethyl ether, carbon bisulphide, turpentine (30 per cent. of No. 4), and benzene, but insoluble in ethyl alcohol, and can be precipitated thereby from ethereal solution. They part readily with hydrogen, and the No. 4, warmed with sulphur, gives off hydrogen sulphide, leaving residual carbon.

With sulphuric acid in the warm, sulphur dioxide is evolved and carbon left, the ash in both instances containing potassium ferrieyanide, but powerful oxidising agents like chromic and manganic acid and chlorine have no effect even at the boiling temperature.

For industrial purposes the resins have many applications. The No. 4 is used for making asphalt lac by boiling 10 parts along with 12 parts of varnish, and 50 parts of a solvent (turpentine or petroleum spirit) with a little white lead (see this Journal, 1896, 267). Mixed with a solid body and treated with sulphur while being passed through rollers and then vulcanised, the same resin gives a product resembling ebonite. These resins can be incorporated with caoutchouc in large proportion without affecting its quality, and they are all suitable for preserving wood and as material for the manufacture of anthracene and benzene.

—C. S.

Charcoal, Methyl Alcohol, and Acetic Acid, Quantities yielded by Different Species of Wood. E. Barillot. Comptes rend. 1896, 122, 469.

The following are the results of experimental trials in the laboratory:—

About $\frac{1}{2}$ cb. metre of the wood was placed in a small retort and subjected to heat, the gases evolved being aspirated through a condenser and washing tower. The distillation was conducted very slowly and regularly, and the quantities obtained are to be regarded as the highest possible.

After addition of lime to the distillate the alcohol was driven off, again distilled after acidification with sulphuric acid, and finally rectified over excess of lime with a Le Bel-Henninger column or other similar apparatus. The density of the alcohol so obtained, containing acetone and ethers, was found by the alcoholometer, and calculated to pure methyl alcohol. The total acidity of the distillate was determined and calculated as acetic acid.

The following table gives the amounts of charcoal and acetic acid in kilos. and the alcohol in litres obtained from 100 kilos. of wood:—

Species of Wood.	Pollard Oak. Elm. Beech. ½ each.	Birch. Willow. Aspen. ½ each.	Old Oak.	Aspen. Willow. ½ each.	Dry Oak. Split.	"Moulée."		Beech.		Elm.		Oak. Saw- dust.	Oak. Saw- mill Waste.
						Round.	Split.	Round.	Split.	Round.	Split.		
Acetic acid	5.90	4.34	3.75	4.42	3.72	6.40	6.15	4.18	5.71	5.00	6.24	1.31	4.31
Methyl alcohol	2.15	1.50	1.46	1.69	1.37	1.95	1.95	1.39	1.76	1.41	1.38	0.38	0.93
Charcoal	23.00	22.00	24.00	22.00	22.50	26.00	26.00	23.00	24.39	24.50	25.00	20.00	24.00

Wood, The Products of the Distillation of (Industrial Experiments). E. Barillot. Comptes rend. 1896, 122, 735.

These experiments, on an industrial scale, were made in retorts of 4½ e.m. capacity. The same woods were used as those employed in the laboratory experiments described in preceding abstract. The delivery of the jets of the distillate as it came over was indicated every 15 seconds in cubic centimetres, and frequent examination of the acidity was made, especially each hour. The acetic acid was converted into calcium acetate. The following table gives the details of the distillation from hour to hour:—

Hours of Distilla- tion.	Distillate, c.c.'s per 15 Seconds.	Acetic Acid.	Hours of Distilla- tion.	Distillate, c.c.'s per 15 Seconds.	Acetic Acid.
		Per Cent.			Per Cent.
1	250	0	8	300	17.0
2	200	3.5	9	350	16.0
3	220	5.0	10	300	15.0
4	300	11.0	11	250	13.0
5	375	13.0	12	250	12.0
6	340	13.0	13	300	10.0
7	300	15.0	14	0	0

REMARKS.—Wood distilled, beech, 1,560 kilos. Coal used, 300 kilos. Crude pyroigneous liquid obtained, 795 litres.

Nature of Wood.	Weight of Wood.	Products obtained.		Products obtained per Cent. of Wood.		Remarks.
		Methyl Alcohol.	Calcium Acetate.	Methyl Alcohol.	Calcium Acetate.	
	Kilos.	Litres.	Kilos.			
Small pieces, entire	1,400	16	116	1.14	8.29	Green wood, eight months cut, small, and in poor con- dition.
Two-thirds grey wood, one-third barked ..	1,600	21	143	1.39	11.59	
Barked	1,800	26	197	1.44	11.10	
Hornbeam logs	1,750	24	211	1.57	12.00	Of good quality and well dried.
Split oak (measured)	1,840	30	195	1.60	10.60	
Beech, split large	1,800	33	198	1.80	11.60	Saw-mill waste.
Oak waste, dry	1,900	16	163	0.84	8.50	

This second table shows the actual quantities of methyl alcohol and calcium acetate obtained, the latter after drying.

These results confirm those obtained in the laboratory, described in the preceding abstract. But the final production of calcium acetate, after drying and baking, does not vary in accordance with the yield stated as acetic acid, the difference being due to variation in the nature of the acids yielded by the different sorts of wood.—E. S.

Kerosene Shale, Improvements in the Treatment of, for the Production of Hydrocarbons and other Products therefrom. C. H. McEuen, London. From J. C. Alexander

and R. C. Beveridge, Sydney, New South Wales. Eng. Pat. 14,617, August 1, 1895.

It has been found that the temperature necessary for the distillation of shale and the generation of the hydrocarbons produced may be attained with great certainty by the employment of a molten metal bath, either lead, zinc, tin, or the like. For carrying out the improved method, different modifications of known means may be employed, by which the shale may be brought in contact with the source of heat required to liberate the desired product. For instance, by means of mechanical conveyors the shale may be passed over, through, or along the molten metal, whilst the products are collected by an air-tight covering placed over the conveyor.—D. B.

Wood, Wood-Waste, and the like, Improvements in and Apparatus for the Dry Distillation of. A. Schmidt, Cassel, Germany. Eng. Pat. 4598, Feb. 29, 1896.

The method consists in blowing, through an injector, heated air at a suitable point, into the discharge pipe of the distilling retort, in order to draw the products of distillation out of the retort immediately they are formed, and to carry them at once into the condenser. By this means a greater yield of products, especially acetic acid, is obtained.—D. B.

IV.—COLOURING MATTERS AND DYES.

Coal-Tar Colour Industry, The Recent Aims of the. L. Gans. Chem. Zeit. 20, 53–54.

THE more recent aims of the coal-tar colour industry have been to supplant dyewoods and dyewood extracts by artificial products. To supersede dyewoods, the author regards of even greater importance than to find substitutes for indigo, inasmuch as better products may be, and in many respects already have been found for the former, whereas indigo cannot be replaced. It is in the azo-dyes

that the author sees promise of ultimate success in supplanting the dyewoods as completely as artificial alizarin has supplanted madder. For most purposes, more especially for the dyeing of cotton, the dyewoods may already be dispensed with, their artificial substitutes giving superior results and being more easy of application.—I. S.

Hæmatoxylin and Brasilin. J. Herzig. *Monatsh. Chem.* 16, 906—918.

FURTHER research has thrown doubt upon the analogy drawn by the author between hæmatoxylin and brasilin on the one hand, and xanthone and allied compounds on the other (*Monatsh. Chem.* 15, 139; this Journal, 1894, 797). The resemblance is due to the fact that all the hydroxyl groups which the compounds contain do not behave similarly on methylation. Hæmatoxylin with five hydroxyl groups, gives a tetra-alkyl derivative insoluble in KOH, and incapable of further alkylation; brasilin with four hydroxyl groups yields a tri-alkyl derivative of similar properties. It is now shown, *firstly*, that these properties hold good for a much larger number of substances than was formerly supposed, and, *secondly*, that the methylation phenomena of hæmatoxylin, &c., and xanthone differ materially.

—R. B. B.

Dyestuffs, Vegetable, Direct Dyeing, Certain Artificially Prepared. V. H. Soxhlet. *Chem. Zeit.* 19, 2295—2296.

Two classes of preparations exist capable of dyeing in a single bath, both being true metallic lakes of vegetable colouring matters. The more soluble lakes are known as "carmine colours," and are suitable for dyeing cotton and other vegetable fibres; the less soluble lakes may be applied in wool dyeing. The latter are unsuitable for cotton, since it is necessary to dissolve the lake in acid, and cotton cannot take up the colouring matter from an acid solution. The carmine colours are sold in the form of liquid extracts and are completely soluble in non-calcareous water. They are prepared by mixing with the dyewood decoctions metallic salts, usually compounds of tin, copper, or chromium, and heating the mixture until a uniform combination ensues. Yellow carmine is made from quercitron bark decoction and stannate of soda; the addition of 1 per cent. copper sulphate yields a greenish-yellow. Red carmine is obtained if stannous chloride replaces the stannate of soda; the colouring matters of the red woods are not suited for lake formation owing to their insolubility. Blue carmine is best prepared from 12.27 per cent. CuSO_4 , 14.15 per cent. $\text{K}_2\text{Cr}_2\text{O}_7$, 25.31 per cent. alum, and 52 per cent. hæmatein. In all cases a slight excess of the metallic salts is employed to ensure the maximum amount of lake being formed. By mixing the three colouring matters described, a variety of intermediate shades is obtained. All the colours are fast to washing and, with the exception of the blue, fast to acids. Dyeing takes place at 50°—60° C., and the dyed material preserves its soft handle. The dye-bath is not exhausted.

Wool cannot be dyed with the carmine colours, and on heating the dye-bath to the boiling point, decomposition takes place. If, however, oxalic acid be first added, the decomposition is prevented and wool is readily dyed in the solution. On the fact of the solubility of the colour-lakes in acid, depends the preparation of the products which dye wool directly. The most important is "direct black," prepared by precipitating logwood decoction with chromium, copper, or iron. Yellow and red dyestuffs are similarly made from quercitron, peachwood, &c. The chief difficulty in their application is that of choosing exactly the right amount of acid. A deficiency causes dyeing to be too rapid and consequently it proceeds unevenly, and the dye rubs off. An excess of acid tends to prevent dyeing, and the colours are extremely fugitive to light. Such an amount of acid should be chosen that the lake is not completely in solution at the beginning of the operation, but is dissolved later on, during the dyeing process.

The nature of the metallic salts used, also influences the fastness to light, iron lakes being more fugitive than those of chromium or copper.—R. B. B.

Indigo-Red and Indigo-Red Sulphonic Acid. J. Fasal. *Mitt. k.k. techn. Gewerbemuseums (Vienna)*, 1895, 307—309.

THE amount of indigo-red (indirubin) present in commercial indigo varies from 1 to 8 per cent. Like indigotin, it is capable of dyeing by the reduction-vat method, and it has been therefore supposed to influence the shade of vat indigo dyes. The production of indigo-red from indigo is long and tedious, as is also its synthesis from indoxyl and isatio. It can be more readily obtained from indophor, a new commercial product introduced by the Badische Anilin und Soda Fabrik, consisting of indoxyl carbonic acid. Indophor is heated with water until evolution of CO_2 ceases, the solution is filtered hot, and the filtrate treated with caustic soda. Indigo-red in a chemically pure state at once separates, in the form of fine red needles. It is only reduced with difficulty, but most easily by means of zinc powder and alkali. The reduced solution can be used for dyeing in the same manner as an indigo vat, and dyes red-violet shades equal in fastness to vat blues. On standing, however, the contents of the vat suffer a change, and the shades dyed become bluer and bluer; the presence of indigotin can be clearly shown. The dyes do not oxidise in the air as quickly as ordinary vat dyes, and this fact, together with the observed greenish fluorescence, indicate the presence of indoxyl, and not indigo-white. It would thus appear that, under the conditions which convert indigotin into indigo-white, indigo-red is changed to indoxyl. Indigo-red has therefore no effect on the shade of vat blues.

A solution of indigo-red sulphonic acid similarly reduced, shows the same alteration on standing, and, on subsequent oxidation, indigo-carmine is obtained. The colours yielded by this sulphonated product are not fast, even to washing with water.—R. B. B.

Colouring Matter [Brown] obtained from Dibromogallie Acid. A. Biétrix. *Bull. Soc. Chim.* 1896, 235—236.

WHEN dibromogallie acid in an alkaline aqueous solution is exposed to the air, a pink coloration is produced, which rapidly turns brown. For the preparation of larger quantities, the acid is dissolved in an excess of ammonia, and a current of air is passed through the solution. After evaporation to dryness on the water-bath, the residue is washed with alcohol to remove impurities, and the ammonium salt remaining, is converted into the colouring matter acid by treatment with dilute hydrochloric acid. The colouring matter dyes wool and silk brown. It is, however, probably of little industrial value, since, according to Koechlin, 1 kilo. of silk requires 300 grms. of the colouring matter to give a good shade.—T. A. L.

Dithiazole Derivatives. C. Lauth. *Bull. Soc. Chim.* 1896, 82—87.

IN 1880, Hofmann obtained oxalamidothiophenol—

by heating acetanilide with sulphur. The constitution of this substance shows it to be allied to dehydrothiitolmidine and primuline, and it was expected that valuable cotton colouring matters would be obtained from it. The compound, after purification and sublimation, melts at about 306° C. On nitration with nitric acid in sulphuric acid solution under varying conditions, a mixture of two dinitro products is obtained, which can only be imperfectly separated. The mixture was therefore reduced with stannous chloride, and the two diamines can be separated by means of the difference in solubility of their hydrochlorides. The bases obtained therefrom both crystallise in yellow prismatic needles, and one of them shows a fine greenish fluorescence in an alcoholic solution. Prolonged boiling of the bases or their salts with alcohol or water causes decomposition; reducing agents act similarly, with evolution of sulphuretted hydrogen. By stopping the reduction as soon as the yellow colour has disappeared, the solution of one base shows the reactions of an ortho- and the other that of a meta-diamine; no *p* diamine could be

detected. Both bases are colouring matters, dyeing unmordanted cottons and animal fibres a bright yellow, which, on oxidation, turns brown. The colouring matter can be diazotised on the fibre and combined with various amines and phenols and their derivatives, giving a variety of shades. The colours are fast to acids and alkalis, but fugitive to light.—T. A. L.

PATENTS.

Orange to Brown Colouring Matters, Manufacture of. O. Murray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 5114, March 11, 1895.

WHEN aromatic *m*-diamines are condensed with formaldehyde, benzaldehyde or its substitution products, so-called "hydro-acridines," are obtained. The present specification describes the preparation of colouring matters from these products by the action of alkylating agents. For instance, 10 kilos. of diamidodimethyldihydroacridine (leuco acridine yellow), 25 kilos. of methyl alcohol, and 10 kilos. of hydrochloric acid are heated in an enamelled autoclave at 140°–150° C. for four hours with agitation. The melt, after cooling, is diluted with water, the colouring matter being precipitated from the filtered solution by salt and zinc chloride. The colouring matters can also be obtained from the methane bases themselves (resulting from the condensation of 2 or 3 mols. of a *m*-diamine with 1 or 2 mols. of formaldehyde or benzaldehyde) by heating them with methyl or ethyl alcohol and sulphuric acid. The colouring matter obtained by heating 20 kilos. of tetramido-ditoly-methane, 60 kilos. of sulphuric acid (66° B.), and 20 kilos. of methyl alcohol for eight hours at 200°–210° C., and separation as in the previous example, forms a brown powder easily soluble in water, giving reddish-brown shades on leather and on cotton mordanted with tin and tartar emetic. The shades can be altered by modifying the proportions and temperatures.—T. A. L.

Colouring Matters [Azines], The Manufacture of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 5797, March 19, 1895.

WHEN α -amido or α -hydroxy-azo sulphonic acids of the naphthalene series containing the azo group meta to a sulphonic acid group are heated with a primary aromatic amine, a substituted eurhodine is obtained, and on prolonging the action at a higher temperature a further substitution takes place in the azine ring, resulting in the formation of a rosinduline derivative, the final product in any case being sulphonated if necessary. The process is thus allied to that already described in Eng. Pat. 8898 of 1893 (this Journal, 1894, 511), but differs essentially from that referred to in Eng. Pat. 21,205 of 1890 (this Journal, 1891, 359). One kilo. of the azo compound obtained by combining diazobenzene chloride with 1,4,3'-naphthylamine disulphonic acid is mixed with 4 kilos. of aniline and 1 kilo. of aniline hydrochloride, and heated with constant agitation for 5 hours to 140°–150° C. When sulphur dioxide is no longer evolved, the temperature is raised to 160° C. until a sample dissolved in alcohol is no longer decolorised by alkalis. The melt is then poured into hot dilute hydrochloric acid, filtered, and the precipitate washed with hot water. The azine sulphonic acid obtained, can be converted into the soluble sodium salt, or by heating with five times its weight of sulphuric acid (66° B.) at 100° C. it yields a readily soluble disulphonic acid, which gives red shades on wool.

—T. A. L.

Dyestuffs [Orange, Red, and Yellow], Derived from Phenolic Bodies, The Manufacture or Production of Chemical Compounds and. P. A. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 8988, May 6, 1895.

AROMATIC hydroxy compounds will condense with primary and secondary amines of the fatty series in presence of formaldehyde under various conditions. For example, 7.5 kilos. of a 40 per cent. formaldehyde solution, 9.4 kilos. of phenol, 50 litres of alcohol, and 13.5 kilos. of a 33 per cent. dimethylamine solution are added together. The formation of the new compound is completed in a short time, and, after distilling off the alcohol, the residue is extracted with hydrochloric acid, the solution filtered, and the filtrate is precipitated with caustic soda, when a colourless oily substance separates out, having the formula $C_{16}H_{13}OCH_2N(CH_3)_2$. The specification contains a list of several substances which have been prepared according to this method. These substances can be obtained in another way by condensing phenols and their substitution products with certain halogen derivatives of primary, secondary, or tertiary fatty alkylamines by means of caustic potash lye. By condensing *p*-nitrophenol according to either of the foregoing methods and reducing the product, it can be converted into *p*-amidophenol- ω -dimethylamido-ethyl ether which can be employed in the production of dyestuffs. By diazotising 1.8 kilos. of the compound with 0.7 kilo. of sodium nitrite and a sufficiency of hydrochloric acid, it will combine with 1.57 kilos. of *p*-xylylene hydrochloride to form a dyestuff which gives brownish-yellow shades on tanned cotton. By substituting β -naphthol for the phenol, a red basic colouring matter is obtained, having the formula $HClH_2NC_2H_4.OC_6H_4.N : N.C_{10}H_6(O)H$, which gives scarlet-red shades on cotton mordanted with tannin. If *m*-amido-phenol be used, more orange shades are produced.—T. A. L.

Chemical Compounds [Stable Diazo Salts], suitable for the Production of Colouring Matters, in Bulk or on Fibre, and other Purposes, the Manufacture of. P. A. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 8989, May 6, 1895.

CERTAIN β -naphtholtrisulphonic acid salts, when added to acid or neutral solutions of tetrazo compounds of *p*-diamines, give crystalline orange-coloured precipitates, which are the β -naphtholtrisulphonates of the tetrazo compounds. For brevity these compounds are termed tetrazo salts. By adding a solution of one of these tetrazo salts to an alkaline solution of β -naphthol, an insoluble diazo compound is at once formed, and the β -naphtholtrisulphonic acid remains in solution, showing an intense green fluorescence. The same process can be carried out on the fibre, the β -naphtholtrisulphonic acid being displaced and combination taking place with the particular dyestuff component employed. For the preparation of one of these tetrazo salts, a solution of 45 kilos. of 2,3,3',1'-naphtholtrisulphonic acid is allowed to run into as concentrated a solution as possible of dimethoxytetrazodiphenyl chloride obtained from 12.3 kilos. of diarsidine and 7 kilos. of sodium nitrite in presence of hydrochloric acid. The tetrazo salt begins to separate immediately, but the precipitation is accelerated by adding salt. The tetrazo salt so obtained, after filtering off, is tolerably stable, and will keep for some time. In place of the above-mentioned β -naphtholtrisulphonic acid, the isomeric β -naphtholtrisulphonic acid may be used, which is obtained, together with an α -naphtholtrisulphonic acid, according to Eng. Pat. 25,074 of 1893 (this Journal, 1891, 1191), by sulphonating 2,3'-naphthalenedisulphonic acid and fusing the naphthalenetetrasulphonic acid so obtained with alkalis. The method of the tetrazo salts serves as a process for separating these α - and β -naphtholtrisulphonic acids, since only the tetrazo salts of the latter are sparingly soluble, and may be filtered off from a mixture of the two which has been treated with a tetrazotised diamine, the filtrate being worked up subsequently for the α -naphtholtrisulphonic acid.—T. A. L.

Amido Bases and Amido Sulpho Acids belonging to the Naphthalene Series, and of Colouring Matters therefrom, Improvements in the Manufacture of. G. W. Johnson, London. From Kalle and Co., Biebrich-on-the-Rhine, Germany. Eng. Pat. 9103, May 7, 1895.

By heating 1.3-naphthol or naphthylamine sulphonic acid, or their sulphonic, hydroxy, or amido-derivatives, in an autoclave with ammonia to 160° — 180° C., 1.3-naphthylendiamines or their derivatives are obtained. For instance, 65 kilos. of 1.3.3'-naphthol disulphonic acid are heated in an autoclave with 30 kilos. of caustic soda lye (40° B.), 50 kilos. of ammonium chloride, and about 300 kilos. of ammonia liquor to 160° — 180° C. for 20 hours. After expelling the excess of ammonia, the residue is acidulated with sulphuric acid and filtered, when the 1.3.3'-naphthylendiamine sulphonic acid crystallises out on cooling. In a similar manner, 1.3'.3-dihydroxynaphthalene sulphonic acid gives 1.3.3'-triamidonaphthalene, and the same product is obtained from 2.1'.3'-amidonaphthol sulphonic acid G; 1.3.4'.2'-naphthol trisulphonic acid yields 1.3.4'.2'-naphthylendiamine disulphonic acid. All these products can be employed for the manufacture of azo colouring matters by combining them with diazo or tetrazo compounds, or else for the production of azines by condensing them with alkylated nitroso derivatives, or oxidation together with alkylated *p*-amido anilines. The tetrazo compound from 9.2 kilos. of benzidine is run into a cold solution of 28 kilos. of 1.3.1'-naphthylendiamine sulphonic acid and 10 kilos. of sodium carbonate in 500 litres of water. After agitation for some hours, the formation of the colouring matter is complete, when it is salted out, filter-pressed, and dried. It dyes a fast red on cotton. The following example describes the formation of an azine colouring matter:—24 kilos. of 1.3.4'-naphthylendiamine sulphonic acid suspended in 100 litres of alcohol are mixed with 19 kilos. of nitrosodimethylaniline and heated on the water-bath for 3—4 hours. The colouring matter separates on cooling in bronzy needles, and dyes wool and mordanted cotton violet.

—T. A. L.

Fast Azo Colouring Matters, especially adapted for Dyeing on Wool, Improvements in the Manufacture of. G. W. Johnson, London. From Kalle and Co., Biebrich-on-the-Rhine, Germany. Eng. Pat. 9454, May 13, 1895.

THESE colouring matters, which are said to be very fast to milling and light, are obtained by sulphonating the disazo compounds from *o*-nitrotetrazodiphenyl and two molecular proportions of a phenol, naphthol, or a carboxylic acid thereof. The mixed disazo compounds are of course equally applicable for the purposes of this invention. 20 kilos. of the product from *o*-nitrobenzidine and two molecular proportions of β -naphthol are dissolved in 200 kilos. of 100 per cent. sulphuric acid and heated to 50° — 60° C. until a sample is completely soluble in dilute sodium acetate solution. The melt is then run into 2,000 litres of water, the sulphonated product filtered off and dissolved in soda-lye. The sodium salt is precipitated from the hot solution, and is filter-pressed and dried. It gives bluish-red shades on wool. A yellow colouring matter for wool is obtained by stirring 20 kilos. of the disazo compound from equimolecular proportions of *o*-nitrobenzidine, cresotic acid, and phenol into 100 kilos. of 100 per cent. sulphuric acid. When all is dissolved, 100 kilos. of fuming sulphuric acid containing 30 per cent. of anhydride are added and the mixture agitated at the ordinary temperature until a sample dissolves in hot water. The melt is then worked up as before.

—T. A. L.

New Azo Dyes, and of Materials for Producing the same, The Manufacture of. S. Pitt, Sutton. From L. Cassella and Co., Frankfort a. M., Germany. Eng. Pat. 9645, May 15, 1895.

THE specification refers to the production of nitro-amido-salicylic acid ($\text{NH}_2 \cdot \text{NO}_2 \cdot \text{OH} \cdot \text{CO}_2\text{H} = 1:3:4:5$), which is obtained by nitrating *p*-amido-salicylic acid in sulphuric acid solution at a low temperature. 77 kilos. of 1.4.5-amidohydroxybenzoic acid are dissolved in 3.50 kilos. of sulphuric acid (66° B.), cooled to 6° — 5° C., and nitrated at a low temperature with 110 kilos. of a mixture of

nitric and sulphuric acid containing 30 per cent. of HNO_3 . When all has run in, the temperature is raised to 15° C. within half an hour, and the melt is then diluted with ice. The nitro compound separates out almost completely, and melts with decomposition at 240° C. It is sparingly soluble in water and gives with sodium nitrite an almost insoluble diazo acid, which reacts very readily with amines and phenols. 20 kilos. of 1.3.4.5-amidonitrohydroxybenzoic acid, after conversion into the sparingly soluble yellow diazo compound, is combined with a solution of 36 kilos. of R salt kept alkaline with sodium carbonate. The colouring matter, which forms at once, separates as a brown precipitate, and dyes wool red from an acid bath. If the nitro-amidosalicylic acid be combined with α -naphthylamine, the amido-azo compound produced can be further diazotised, and on combination with R salt a bluish-black colouring matter is obtained which dyes wool blue-black, fast to washing, and if mordanted with chrome or alumina, the dyeing is perfectly fast to milling. Similar colouring matters of a somewhat bluer shade may be obtained from the 1.5.2.3-amidonitrohydroxybenzoic acid melting at 220° C.—T. A. L.

Dyestuffs [Azines] and Materials therefor, The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co." Elberfeld, Germany. Eng. Pat. 9794, May 17, 1895.

IN Eng. Pat. 6176 of 1895 (this Journal, 1896, 269) the patentees describe the preparation of so-called aliphyl-*p*-amidobenzyl-*o*-toluidines. According to the present specification, it is shown that the benzyl group may be replaced by other alkylating groups, such as methyl or ethyl. A solution of 20 kilos. of phenyl-*p*-amido-*o*-toluidine, 11 kilos. of ethyl bromide, and 40 kilos. of alcohol, is heated in an autoclave for 10 hours to 150° — 175° C. The product is mixed with a small quantity of hydrochloric acid and dissolved in boiling alcohol. The base is precipitated by means of sodium carbonate and is purified by crystallisation from petroleum ether, when it melts at 60° C. having the formula $1.2.4.\text{C}_6\text{H}_3(\text{CH}_3)(\text{NH}\cdot\text{C}_2\text{H}_5)(\text{NH}\cdot\text{C}_6\text{H}_5)$. Colouring matters of the azine series are obtained from this and analogous compounds by similar processes to those given in the specification already referred to. As an example of one of the methods employed, 21 kilos. of phenyl-*p*-amido-methyl-*o*-toluidine and 43 kilos. of benzene-azo- α -naphthylamine hydrochloride are heated on the water-bath in presence of 20 kilos. of glacial acetic acid until the azo compound is no longer distinguishable. About 2 litres of hydrochloric acid (20° B.) and a sufficient quantity of water are added, and the dyestuff is salted out, being purified, if necessary, by dissolving in water and again salting out. The colouring matter gives bluish-red shades on tanned cotton fast to alkalis, acids, and light.—T. A. L.

New Colouring Matters [Azo-Dyestuffs], Manufacture of. C. D. Abel, London. From A. Fischesser and Co., Lutterbach, Alsace, Germany. Eng. Pat. 10,470, May 27, 1895.

THE colouring matters described are obtained by combining diazo or tetrazo compounds with the 1.1'-amido-naphthol disulphonic acid of Eng. Pat. 13,203 of 1894 (this Journal, 1895, 479). Aniline, nitraniline, α - or β -naphthylamine after diazotisation may be combined with the acid in an alkaline or acid solution, the colouring matters obtained, dyeing wool red to reddish-violet shades from an acid bath. Amido-azo compounds such as amido-azobenzene or naphthalene, give red to dark violet-blue shades. Tetrazo derivatives from benzidine, toline, or diaminidine, &c., when combined with two molecular proportions of the amidonaphthol disulphonic acid, give colouring matters dyeing unmordanted cotton violet-blue to greenish-blue. Instead of employing two molecular proportions of the same acid, different acids may be used, one being the new acid, the resulting diazo compound dyeing still darker shades. Finally, reddish-violet cotton-colouring matters are obtained by combining the diazo compounds of dehydrothiitoluidine and its homologues and sulphonic acids with the acid sodium salt of the 1.1'-amido-naphthol disulphonic acid.—T. A. L.

Colouring Matters, Improvements in the Manufacture of. H. H. Lake, London. From "Farbwerk Mülheim," Mülheim a M., Germany. Eng. Pat. 10,668, May 29, 1895.

THE mono-acidyl derivatives of *m*-phenylene or *m*-tolylene diamine combine with diazo or tetrazo compounds to form colouring matters and new intermediate products which can be diazotised and combined further with other components. Some of these reactions can be carried out on the fibre, and the compounds produced yield, on saponification, other azo dyes which it has not hitherto been possible to obtain. One molecular proportion of β -naphthylamine disulphonic acid G, after diazotisation, is combined with one molecular proportion of acetyl-*m*-tolylene diamine. The resulting compound is again diazotised and combined with one molecular proportion of β -naphthol in an alkaline solution. After salting out the dyestuff, it is saponified by dissolving 1 kilo. of it in 30 litres of water and 15 kilos. of 33 per cent. soda lye and boiling for two hours. After neutralising the greater part of the alkali with hydrochloric acid, the new dyestuff is salted out. The saponification can also be effected by dissolving, for instance, 1 kilo. of the dyestuff derived from β -naphthylamine disulphonic acid, acetyl-*m*-tolylenediamine, and β -naphthol disulphonic acid R in 25 litres of water, adding about 5 kilos. of 30 per cent. hydrochloric acid, and boiling under an inverted condenser. The violet liquid which is obtained after some time, deposits the saponified dyestuff on cooling. This is converted into its sodium salt in the usual manner, and dyes wool bluish-black from an acid bath. The tetrazo derivative from 38 kilos. of diamido-stilbene disulphonic acid is poured into an alkaline solution of 34 kilos. of acetyl-*m*-tolylene diamine. After salting out, the colouring matter dyes unmordanted cotton red from an alkaline bath, and can be further diazotised and combined on the fibre, giving with β -naphthol a violet-black, with α -naphthylamine a black, and with *m*-phenylenediamine a brown colour. In addition to the acetyl compounds, the use of benzoyl-*m*-phenylene diamine and of *m*-phenylene and *m*-tolylene oxamic acid is also claimed.—T. A. L.

Methyl Aniline, Ethyl Aniline, Para-anisidine, and Para-phenetidine, Lactyl Derivatives of. J. Y. Johnson. From "The Chemische Fabrik vorm. Goldenberg, Geronmont, and Co.," Winkel. Eng. Pat. 10,676, May 29, 1895.

THE preparation of the lactyl derivatives of methyl and ethyl aniline, para-anisidine, and para-phenetidine by heating the α -halogen propionyl derivatives of the bases with salts of carboxylic acids in aqueous or alcoholic solution under pressure or otherwise, is claimed in this patent. The process is carried out briefly as follows:—5 kilos. of α -brom-propionyl bromide are dissolved in 20 litres of well cooled and dry ether, and 6.34 kilos. of para-phenetidine added. The ether is distilled off and the product washed with water and re-crystallised from boiling alcohol. Other similar compounds are prepared in an analogous way.

They are converted into lactyl derivatives by boiling with sodium acetate; for example, 20 kilos. of α -brom-propionyl para-phenetidine and 12–20 kilos. of crystallised sodium acetate are dissolved in 90 per cent. alcohol and boiled with reversed condenser; the reaction being complete, the alcohol is distilled off and the residue washed with water; it consists of pure lactyl para-phenetide.—T. E.

Colouring Matters Dyeing Yellow with Mordants, Manufacture of. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 12,221, June 24, 1895.

By combining the diazo compounds of aromatic amines containing an alkylated hydroxy group, with phenol carboxylic acids, yellow mordant dyestuffs of considerable strength and solubility are obtained. The solution of the diazo compound from 42 kilos. of *m*-amido-*p*-cresol methyl ether ($\text{CH}_3 : \text{OCH}_3 : \text{NH}_2 = 1 : 4 : 3$) is run into a cold solution of salicylic acid kept alkaline. The mixture is heated to boiling, the excess of alkali neutralised with an acid, and the colouring matter is salted out in yellow crystalline needles. It dyes chrome-mordanted wool a

bright yellow. More greenish shades may be obtained by employing *p* or *m*-amidophenol ether in place of the *m*-amido-*p*-cresol ether mentioned in the example.—T. A. L.

Polyazo Dyes [Cotton Dyes] of the Benzidine and Analogous Series, The Manufacture and Production of. J. Y. Johnson, London. From "The Badische Anilin and Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 12,303, June 25, 1895.

THIS is an extension of Eng. Pat. 6697 of 1895 (this Journal, 1896, 195), and describes the application of the process, oxidation of simple azo dyes of the benzene series, to more complex derivatives. Such derivatives are:—(1.) Secondary diazo dyes of the general formula B.N:N.Z.N:N.X , where B is the radicle which undergoes oxidation, Z is a middle component, which after combination is capable of further diazotisation, such as α -naphthylamine or aniline, and X is any dyestuff component. (2.) Primary disazo dyes of the formula B.N:N.U.N:N.B' , where U is an end component capable of combining with 2 diazo groups, such as *m*-phenylene diamine or resorcinol. (3.) Polyazo dyestuffs of the formula—

(4.) Disazo dyes with *m*-phenylene diamine as first component. Mixtures of the simple azo dyes with any of the above polyazo dyes may also be employed. The following example, illustrating the process, is given. About 10 kilos. of amido-azobenzene-azo- β -naphthol disulphonic acid is dissolved in 150 kilos. of concentrated sulphuric acid at -5°C ., and, with constant agitation, about 3 kilos. of manganese peroxide (80 per cent. MnO_2) is stirred in. The solution, at first yellowish-red, changes to violet, and when the reaction is complete, the melt is poured on to ice together with a little sodium bisulphite. After filtering, washing, and pressing, the colouring matter is converted into the sodium salt, and may be purified if necessary by redissolving. It gives red shades on unmordanted cotton. A blue-black dyestuff for unmordanted cotton is obtained by oxidising the disazo dyestuff obtained by combining diazotised aniline and naphthionic acid with dihydroxy naphthalene disulphonic acid H.—T. A. L.

Colouring Matters [Primuline], Improvements in. Brooke, Simpson, and Spiller, Ltd., and W. S. Simpson, Hackney Wick, London. Eng. Pat. 12,442, June 27, 1895.

IN the manufacture of primulose (obtained by sulphonating the product of the reaction of sulphur on *p*-toluidine), the sulphonic acid hitherto has been dissolved in an alkali and the solution evaporated to dryness. According to the present specification, the patentees wash the primuline sulphonic acid and, after drying it in a hydro-extractor or in a drying-room, grind the free acid with a definite proportion of sodium carbonate sufficient to convert the insoluble primuline sulphonic acid, when dissolved in the dye-bath, into the soluble alkaline salt known as primuline.—T. A. L.

Polyazo Dyes, Blue, Bluish-Black, or Greenish-Black, on Vegetable Fibre or on Silk, Improvements in the Production of. J. Y. Johnson, London. From "The Badische Anilin and Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 13,032, July 5, 1895.

IN Eng. Pat. 1002 of 1895 (this Journal, 1896, 28), the production of black shades on vegetable fibre or silk is described, consisting in padding the goods with a solution of an azo dye, and combining this on the fibre with a diazo or tetrazo compound. It has now been discovered that the black dyestuffs obtained by means of tetrazo compounds are capable of further combination with dyestuff components, such as β -naphthol or *m*-phenylene diamine. The process is carried out as follows:—About 100 kilos. of cotton are dyed in a nearly boiling bath for an hour, containing 1 kilo. of the dyestuff from one molecular proportion of 1.1'.4'-amidonaphthol sulphonic acid, 5 kilos. of calcined soda, and 15 kilos. of sodium sulphate in 3,000 litres of water. Wash out with cold water, and pass the goods through a 2 per cent. solution of tetrazo ditolyl acetate, taking sufficient of the tetrazo compound for the dyestuff present. During this process the blue colour is converted into a greenish-

black. After well washing in cold water, the goods are passed through a solution containing 15 kilos. of β -naphthol, 50 kilos. of Turkey-red oil, and 4 kilos. of caustic soda in 1,000 litres of water. The combination takes place at once, and bluish-violet to bluish-black shades are obtained.

—T. A. L.

Diazo Compounds and Azo Dyes, New Nitrosamine Compounds suited for Use in the Preparation of; The Manufacture and Production of. J. V. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 13,160, July 12, 1895.

This is an extension of Eng. Pat. 20,605 of 1893, and of Eng. Pat. 2397 of 1894 (this Journal, 1894, 1189, and 1895, 147), and describes the production of nitrosamines from amido-azobenzene or its homologues, and from benzene-azo- α -naphthylamine. As described in the second of the above-mentioned specifications, it is necessary to employ a strong alkali lye and a tolerably high temperature. One kilo. of a 15 per cent. paste of diazo-azobenzene chloride is stirred into 2 kilos. of caustic soda-lye (40° B.) below 5° C., 3 kilos. of powdered caustic soda are then stirred in below 10° C., and the mixture is heated until a sample gives no trace of a dyestuff when mixed with β -naphthol in a solution only slightly alkaline. This occurs at about 130° – 150° C., and the nitrosamine sodium salt floats up, when it can be mechanically separated from the melted caustic soda. It can be further purified by crystallisation from water.—T. A. L.

Rhodamin Series, Products related to the; The Manufacture and Production from Phthalonic Acid; J. V. Johnson, London. From "The Badische Anilin und Soda Fabrik," Ludwigshafen, Germany. Eng. Pat. 11,135, July 24, 1895.

By condensing phthalonic acid (obtained by oxidising naphthalene with potassium permanganate, Ger. Pat. 79,693) with alkylated m -amidophenols, the final products obtained are rhodamines. The reaction takes place in two stages, and if one molecular proportion of phthalonic acid be heated with 2–3 molecular proportions of a di-ethyl- m -amidophenol to about 105° C., a crystalline powder is obtained very sparingly soluble in water and alcohol, but easily in glacial acetic acid, dilute hydrochloric acid, alkalis or carbonates, and melting at about 175° C. When this intermediate product is heated to a higher temperature, with or without a condensing agent, it is converted into a rhodamine dyestuff. It follows, of course, that the two operations may be combined, and the melt raised at once to the higher temperature. An alternative method for obtaining the rhodamines is to treat the intermediate compounds with oxidising agents, the following being a typical example of the method employed. About 50 kilos. of dialkyl- m -amidophenol and 20 kilos. of phthalonic acid are heated for six hours to about 105° C. until a solid mass is obtained. In order to isolate the intermediate product, the melt, after extraction with water, is dissolved in dilute hydrochloric acid containing about 16 kilos. of pure HCl, filtered, and the intermediate product is separated by adding a solution of 90 kilos. of crystallised sodium acetate, when it is filtered and dried. About 50 kilos. of the intermediate product, either crude or purified, is dissolved in 750 kilos. of dilute acetic acid (containing 30 per cent. pure $C_2H_3O_2$). To this solution, 21 kilos. of potassium persulphate are slowly added, and the mixture is heated on the water-bath until a sample made alkaline with dilute soda lye is no longer blue or violet. After cooling, the dyestuff is salted out and purified by any well-known methods.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Cellulose, Increase in Temperature of, on Absorption of Atmospheric Moisture. Clayton Beidle and O. W. Dahl. Chem. News, 73, 1896, 180.

The authors have determined the gain in weight and also the rise in temperature when the following anhydrous celluloses are exposed to the air:—(1.) Cotton wool. (2.) Cotton wool mechanically pulverised so as to reduce the fibres to about one-twentieth of their former length. (3.) Coarsely ground viscid (an amorphous cellulose). (4.) Finely ground viscid.

(1) and (2) take about 60 minutes to come to a constant weight. (1) gains considerably less than (2). The two viscid samples took nearly four hours to come to a constant weight, but the finely powdered gained considerably less than the coarse. The curves given for the increase in weight show that there is increased regularity with the increased subdivision of the cellulose. The results show also that this holds good whether the cellulose is in a fibrous or amorphous condition.

The temperature curves in which the temperature of the air is reduced to a straight line, show that cotton reaches a maximum of about 4.5° F. in 10 minutes. The temperature gradually falls, and reaches the atmospheric temperature in about 60 minutes. Disintegrated cotton reaches a maximum of 7° F. in 20 minutes, and takes much longer to fall. The curve is also much more regular than that of cotton wool. Both kinds of viscid fall suddenly below the atmospheric temperature during the first minute. They reach the atmospheric temperature again in about two minutes. They reach a maximum of 7.5° F., and fall slowly but somewhat irregularly. It appears that each cellulose has a characteristic temperature curve. In each case the degree of fineness affects the regularity of the curves.—C. B.

PATENTS.

Soluble Bodies, Envelope or Coverings for Use in Preserving; An Improved. A. Le Chatelier, Paris, France. Eng. Pat. 7192, April 8, 1895.

See under I., page 341.

Textile Fibres on Slubbing, Intermediate, or Roving Bobbin or Cop Tubes, Preparing or Spinning, and subsequently Bleaching, Improvements in and in Means for. J. H. Lees-Milne, Oldham. Eng. Pat. 7685, April 17, 1895.

The fibrous material is prepared in the form of a bobbin on a perforated tube fixed detachably on the tube of a slubbing, intermediate, or roving frame, or it is spun on the perforated tube in the form of a cop. The bobbins or cops are placed in a bag and boiled with water, and subsequently bleached in a vacuum kier. The perforated tubes are preferably made of sheet metal rolled into the form of a tube with a longitudinal division or split.—R. B. B.

Textile Materials, Treating, in order to Render them less liable to be Spotted or Soiled, An improved Process for. J. B. Rapetout, Asnières, France. Eng. Pat. 8053, April 23, 1895.

The materials, after having been washed, are immersed in a clear aqueous bath containing 3 per cent. of alum, and 0.8 per cent. of carbonate of soda. After that they are plunged into a solution of acetate of alumina of 5° B., this latter solution being compounded with 30 grms. of Marseilles soap per litre for cotton and silk, and the latter being further treated in a bath of 10 grms. of acetic acid of 7° B. per litre of water.—H. S.

Flax and other Textile Materials, Retting and Drying; Improved Process and Apparatus for. W. P. Thompson, Liverpool. From R. C. L. E. de Swarte and J. M. E. Doumer, Lille, France. Eng. Pat. 8642, May 1, 1895.

The apparatus consists of a closed cylindrical basin enclosed in an open metal tank, and is so constructed that a vacuum can be produced in the inner vessel, or a current of hot air can be drawn through the same. By producing a vacuum, the air is removed from the substance to be treated so that

the liquid subsequently thoroughly penetrates the material. The retting is accomplished by a fermentation, the agent being a microbe "amylo bacteria." It is developed in hot water of 38°—48° C. Drying is effected by filling the outer vessel with hot water and producing a vacuum in the inner vessel, or a current of hot air is drawn through the latter. In an alternative process the vacuum is dispensed with.

—R. B. B.

Jute, Retting or Steeping; Improvements in. C. Bergmann, Meissen-on-the-Elbe, Germany. Eng. Pat. 10,450. May 27, 1895.

THE jute is treated with the retting or steeping liquid in closed steam-jacketed vessels. The advantages over the ordinary process are said to be:—(1) the influence of external temperature is removed; (2) there is no loss of liquid by evaporation; (3) there is no difference in the activity of fermentation between the inner and outer layers of material.—R. B. B.

Felt, Fibrous Bituminous; Improvements in the Manufacture of. E. Nelson, London. Eng. Pat. 16,399, Sept. 2, 1895.

THE material described is composed of alternate layers of fibrous felt and ductile sheet metal. The metal is coated on both sides with pitch or other bituminous substance, and pressed between the layers of felt, to which it adheres. The sheets so formed are especially suited for damp-course materials in the foundations of buildings, roofing, &c.

—R. B. B.

Noils and other Wool and Hair Waste, Stained with Pitch, Tar, and other Colouring Material, Cleansing by Chemical Means; Process for. E. Balatsch, C. Herold, A. Bayer, all of Brunn, Austria. Eng. Pat. 16,766, Sept. 7, 1895.

THE material is treated with an aqueous emulsion of heavy or light oils of tar, prepared by means of soap. It is stated that the tarry clumps or clods of noils, &c. are well softened and afterwards easily removed by means of this treatment.—H. S.

Wool, Scouring and Degreasing; Improvements in. G. Malard, Paris, France. Eng. Pat. 23,882, Dec. 13, 1895.

THE material is placed upon a travelling belt which passes above a series of tanks containing the cleansing liquid. This liquid is pumped up into sprinklers arranged above the belt, and falls from these on to the wool to be treated, and then the liquid returns by means of an automatic arrangement to its own or to the next tank. The wool is first treated with the liquid containing most of the grease, and finally with that containing the least, or with pure water or other suitable liquid.—H. S.

Wool, the Treatment of; [Cleansing], Improvements in and relating to Process of and Apparatus for. J. C. Anderson, Chicago, U.S.A. Eng. Pat. 2213, Jan. 30, 1896.

A PROCESS for cleansing wool by means of volatile solvents. The wool is placed in steam-jacketed vessels, where it is moistened with water, and heated by admitting steam to the jacket space. The steam generated in the vessel serves to soften and loosen the fatty matters and also to vaporise certain volatile constituents, which are led away and condensed.

In the treatment with hydrocarbons which follows, the essential feature is that the solvent, instead of repeatedly passing through the wool and thus becoming more and more highly charged with fatty matter, is subjected to evaporation and condensation after each passage through the wool, whereby the wool is several times treated with pure solvent.—R. B. B.

Linoleum, Kamptulicon, and other Floor Coverings, Improvements in or relating to the Manufacture of. K. Kléc, Lancaster. Eng. Pat. 18,937, Oct. 9, 1895.

THE object of this invention is the manufacture of linoleum, the design of which, instead of being printed on the surface,

passes through the whole thickness, and therefore cannot be worn off. For this purpose a number of differently coloured sheets of linoleum are prepared, the colouring matters being mixed with the material during manufacture. These sheets are cemented together according to a design, and form a block or cube. From these blocks slices are cut which are again cemented into other blocks, showing in cross section the pattern required. Finally, cross sections of these are taken and used, either directly or mounted on suitable fabrics, as floor coverings.—R. B. B.

Peat Fibres, Chemically Prepared; a New and Improved Process for the Manufacture of. C. Geige, Düsseldorf, Germany. Eng. Pat. 20,501, Oct. 30, 1895.

THE patentee states that chemically prepared pure peat fibres are obtained by placing the cut peat in a weak alkaline bath, continuously agitated for several hours. After having been dried, the fibres are disintegrated by suitable opening machines, and then they are placed for several days in a warm bath containing yeast and dilute sulphuric acid, in order to decompose the starch and vegetable albumin present. After this treatment, the fibres are washed and subjected in closed vessels under pressure to the action of hot ether, benzene, petroleum spirit, or other fat solvents. After another washing, the peat fibres are boiled with dilute acids or alkalis, the suitable strength being usually 1 to 3 per cent. Finally, the material is again thoroughly washed, and, if desired, bleached in the usual manner.—H. S.

Waterproof, Textile, and other Fabrics, Ornamental and other Designs upon, Improvements in the Production of. L. Mistovski, Heywood, Lancashire. Eng. Pat. 21,511, Nov. 13, 1895.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Piece-Goods, Woollen; the Bleaching of. A. Lohmann. Färber. Zeit. 7, 35—37 and 49—50.

THE author gives a full description of the well-known processes of bleaching piece-goods in sulphur chambers, and also of liquid bleaching with sulphurous acid and with hydrogen peroxide. He recommends as the most perfect bleach, after treatment in the sulphur chamber, to wash with warm water, rinse in dilute ammonia, then pass into very dilute hydrogen peroxide, in order to remove sulphurous acid, and finally to tint with some blue or violet dyestuff, to obtain the desired tone of reddish- or bluish-white. This is better than applying the dyestuff before bleaching.

In bleaching with hydrogen peroxide, the bath is used in a faintly alkaline state, but when kept for further use it is rendered more stable by making it slightly acid, and then adding an excess of ammonia before use.—R. B. B.

Alizarin, Soluble, and its Application in Turkey-Red Dyeing. H. Schaeffer. Bull. Soc. Ind. Mulhouse, 1896, 81—85.

THE so-called "soluble alizarin" consists of sodium boron-alizarate, and by its use there can be produced on cotton, pink and red shades of equal fastness to light and other agencies to those produced by the ordinary Turkey-red process, and less liable to rub off. Schmid has described (Chem. Zeit. 19, 776—778; this Journal, 1895, 653) a process in which the alizarin is applied before mordanting, but he states that the method is only suitable for pinks. However, with this order of operations the boron-alizarate will yield full and bright reds. Soluble alizarin is produced by dissolving one part of alizarin and two parts of borax in boiling water and evaporating the solution to dryness. The residue is ground to powder, and is well suited for exportation, being un-

affected by extremes of temperature. A solution of soluble alizarin in distilled water forms a very delicate test for the presence of lime in water, giving a flocculent precipitate with the merest trace of a calcium salt.

Method of Dyeing.—The goods are prepared with oil in the usual manner, and dried; then padded in the alizarin solution, to which a little Turkey-red oil has been added, squeezed, and passed through the mordant bath. They are left piled for 15–20 minutes, and then well washed to remove uncombined mordant. The padding with alizarin, mordanting, and washing operations are repeated as often as is necessary to obtain the desired shade. After the last mordanting the goods are not washed, but are padded in a solution of acetate of tin at $\frac{1}{2}$ B., then dried, steamed, washed, and finally soaped, with the addition of a little silicate of soda.

The mordant consists of acetates of aluminium, calcium, and tin, with acetic acid, or may be prepared from aluminium and magnesium sulphates, sodium carbonate, stannous chloride, and calcium acetate.—R. B. B.

Indigo Vat, The Stannous Chloride; and its Application instead of the Hydrosulphite Vat. C. Dreher. *Färbet. Zeit.* 7, 145–147.

THE hydrosulphite vat possesses the advantage over other indigo vats, of much greater penetration of thick or closely packed materials. This doubtless results from the fact that in this vat alone is the reducing agent present in a soluble form. It is therefore sought to discover some process having this advantage, without the great disadvantage of the unstable nature of the hydrosulphite. The reducing agent must be in alkaline solution but not too strongly alkaline, or the resulting shades are weak and dull and animal fibres are injured. This defect of too great alkalinity is shown by the proposed alkaline glucose vat.

Useful results are obtained by using an alkaline solution of a stannous salt, e.g., a solution of stannous chloride in caustic soda. The vat is thus prepared:—

Steep 500 grms. of ground indigo in four times the amount of hot water, and grind together into a paste. Then make the following solutions (1), 250 grms. of glucose in 2 litres boiling water, (2) 500 grms. of caustic soda in 5 litres warm water, (3) 500 grms. of stannous chloride in 1.5 litres warm water. Add solution (3) to solution (2) with constant stirring. The resulting liquid must be quite clear. 750 grms. of indigo paste are well mixed with solution (1), the mixture slowly heated to 60° C., and this temperature maintained while the alkaline tin solution is gradually stirred in. A clear golden yellow liquid results. This, diluted with 20 litres of water, is the required vat, in which the goods are dyed as usual. After the necessary number of dips, the goods are washed in water containing a little hydrochloric acid, then washed with water and dried. The resulting dyes are very bright and quite even, and penetration is complete. The fastness is considerably improved by subsequent steaming for a short time without pressure.—R. B. B.

Aniline Black (Grawitz's) with Sulphocyanides. Henry Schmid. *Chem. Zeit.* 1896, 20, 51–52. (See also this Journal 1882, 361.)

A criticism of Grawitz's process (*Eng. Pat.* 2614, 1895; this Journal, 1895, 569). Author states that with the formula given (1 mol. aniline salt, $\frac{2}{3}$ mols. sodium chlorate, and 1 mol. ammonium sulphocyanide) at most a very indifferent grey is obtainable, by whatever method of steaming. In the presence of vanadium, the sulphocyanide may not exceed $\frac{2}{3}$ mols., or 20–25 grms. per litre of dye. Better results are obtainable if manganese chloride be substituted for the vanadium, and with 1 mol. of aniline hydrochloride, $\frac{2}{3}$ mols. NaClO_3 , $\frac{2}{3}$ mols. NH_4CNS , and $\frac{1}{4}$ mols. $\text{MnCl}_2 + 4 \text{ aq.}$, in the proportion of 100 grms. of aniline salt to the litre, the black by steaming is satisfactory as regards its quality, but offers no advantages over the ferrocyanide black. The new black of Grawitz is said to be inferior to and dearer than Prud'homme's black, to turn green, and it is moreover alleged that the fibre is tendered. Another objection is, that the dye-liquor rapidly decomposes. For oxidation black, the sulphocyanide process offers no special advantages, Witz having pointed out as early as 1881 (this Journal

1882, 361) that ammonium sulphocyanide retards the development of the black, the effect being already noticeable with 10 grms. to the litre of dye, and above 30 grms., the development becomes difficult.—I. S.

Tissue Printing, Recent Progress in. Oesterr. Wollen- und Leinen-Ind., 1896, 15, 9.

Silk Tissues.—The colour-mixtures employed, are in general similar to those which are used in printing woollen fabrics, but certain shades, especially dark browns, are not easy to obtain on silk.

Reserve-patterns are still printed with melted fat and wax mixtures, but the grounds are now chiefly dyed with the basic colouring matters.

For discharge-printing, the tissues are dyed with acid azo-dyestuffs, the discharges being obtained with zinc dust or stannous salts.

Mixed Silk and Cotton Tissues.—Large quantities of these are printed. The colours applied, with few exceptions, are the same as those employed in calico printing, basic dyestuffs being principally used for bright colours.

Reserve-effects are produced on black grounds by padding the mixed fabrics with an aniline black mixture, drying at a low temperature, printing, and developing the black in the ordinary manner.

Discharges are effected with stannous salts or zinc dust on grounds dyed with the cotton-substantive azo-colouring matters.

Cotton Tissues. Bleaching.—For scouring for printing purposes, the apparatus of Thies and Herzig and of F. Gebauer is finding increased employment.

Several large concerns are experimenting with electrolytic bleaching processes.

Azo-colouring Matters formed on the Fibre.—A bluish shade of red is obtained from diazo-*p*-nitrobenzene and "naphthol R" (*Eng. Pat.* 16,987, of 1894; this Journal, 1895, 803), a mixture of β -naphthol with 2'-2'- β -naphthol-sulphonie acid.

Several derivatives of *p*-nitraniline, sent into commerce under the names of nitrosamine red (*Eng. Pat.* 20,605 of 1893; this Journal, 1894, 1189), azophor red (*Eng. Pat.* 21,227, of 1894; this Journal, 1895, 962), and paranitro red (*Eng. Pat.* 18,429 of 1894; this Journal, 1895, 800; 1896, 27), possess the advantage, it is stated, of giving diazo-salt solutions, which are more stable than those ordinarily prepared from *p*-nitraniline. It is discovered, however, that the diazo-solutions directly obtained from *p*-nitraniline may be kept for a moderate length of time in the absence of sodium acetate, a salt which is usually added to them. It is advisable, therefore, not to add this salt until immediately before the solutions are required for use.

The blue azo-colour from dianisidine is not in extensive use, owing partly to the inability of the colour to completely resist the action of weak acids (e.g., those of the perspiration), but primarily to the difficulty of obtaining even shades of it.

Benzidine is considerably used, along with *o*-nitraniline and dianisidine, for various shades of brown, puce, &c.

The "azo-blacks," for printing on calico prepared with sodium β -naphtholate, have not met with much success, partly no doubt owing to the fact that logwood-black mixtures, acidified with acetic acid, may be used for the purpose. In the black and scarlet style, aniline black is printed along with a thickened solution of sodium β -naphtholate, and after the black has been developed, the fabric is padded on its printed surface with a solution of a diazo-*p*-nitrobenzene salt.

For resisting the formation of the naphthol-azo colours, potassium bisulphite is in many cases found to be a satisfactory agent. The red from *p*-nitraniline is not perfectly resisted by it, when oil compounds are employed in the β -naphthol preparation-solution for the cloth, but in their absence a pure white is obtained. The shade of red, however, is rather dull and yellow.

White and colour reserves, under *p*-nitraniline red and α -naphthylamine chloride, are largely produced.

No means have as yet been discovered for completely resisting the azo-colours from benzidine. The reserve-effects on grounds coloured with these, are consequently, confined to colour-patterns.

It is important that the apparatus used in the development of the azo-colours on cotton shall be so constructed that the immersion of the tissue in the diazo-salt solution (contained in the trough of a mangle, for example) is of very brief duration, the combination proceeding and becoming completed as the tissue afterwards passes in the air over a system of rollers, prior to being washed and soaped.

Basic Colouring Matters.—Instead of printing the discharge-mixtures after mordanting with tannic acid, this is now deferred until the tannic acid has been combined with antimony oxide, better results being thus obtained. The cloth, after rinsing, is dyed various colours: navy blue, green, red, &c.

This process, however, seems likely to be superseded by a method of discharging after padding or dyeing with the colouring matters in question, which consists in applying an oxidising mixture of sodium chlorate and potassium ferrieyanide (such as is used for discharging indigo) and steaming; pigments, with albumin, being added for colour-discharges.

Aniline Black.—A new method of obtaining reserves under this colour is to print a mixture of zinc oxide and sodium acetate or potassium thiocyanate, for white, with basic or cotton-substantive colouring matters, or pigments and albumin for colours, and to pad with an aniline black mixture, and steam-age, &c., as usual.

The padding-mangle employed is provided with three bowls, two for squeezing and one for supplying the colour-mixture to the lower of the two squeezing-bowls. The cloth passes between the squeezing-bowls and then over steam-heated drying-cylinders.

Cotton-Substantive Dyestuffs find important and increasing application in dyeing cotton fabrics for printing discharges upon, and in tinting grounds, being principally applied for the latter object in the starch-paste used in the process of finishing.

Indigo.—Kalle's salt (Eng. Pat. 4287 of 1893; this Journal, 1893, 988; and 1894, 145) and the more recently discovered "indophor" (Eng. Pat. 9291 of 1894; this Journal, 1895, 477), are not much used. Very fast blues, similar in shade to those obtained from indigo, but more readily and economically produced than these, are obtained from various colouring matters now available, of which brilliant alizarin-cyanine may be cited as an instance.—E. B.

Printing, Direct, of Basic Dyestuffs on a Ground dyed with Substantive Colouring Matters. E. Grossmann. *Färber Zeit.* 7, 131—132.

The valuable property of the direct cotton dyestuffs of acting as mordants for basic colouring matters may be made use of in printing, by printing a solution of a basic dyestuff thickened with starch and gum tragacanth on cotton dyed with a "direct" dyestuff. After printing, the goods are steamed and then soaped at 40° C. The process is much simpler than the discharge method, no stannous chloride or tannin being required, nor is the treatment with tartar emetic necessary. Tartar emetic affects injuriously many direct dyes, e.g., Chrysamine and Chicago Blue. The effects produced differ from the discharge effects with the same dyestuffs, since the pattern does not show the colour of the printed dyestuff, but a mixture of this and the ground colour. For instance, with Chrysophenine G and Malachite Green a bright yellowish-green results, with Congo Orange R and Methylene Blue 2 B, a black, and so on. The fastness of the colour compares favourably with that of discharge colours.—R. B. B.

Colours, Alkaline Discharge, on Turkey Red. B. Maslowsky. *Färber Zeit.* 7, 33—35.

TURKEY-RED calico, either plain or printed with fast colours, is in great demand in Russia. Formerly the printed fabrics were produced by hand printing with bleaching powder discharge colours, but, since the introduction of roller printing, alkaline discharge colours have been employed. Turkey red is dyed in two shades, the yellower for all-red fabrics or those printed in black, the bluer shade for white and coloured discharge printing. For the latter is used an

Alizarin containing 70—73 per cent. of Flavopurpurin, 20—22 per cent. of Alizarin, and 7—8 per cent. of Anthrapurpurin.

Printing with Black.—A strong Vanadium aniline black is employed; after printing, the goods are subjected to oxidation, passed through a weak soda and chalk bath with or without the addition of $\text{Na}_2\text{Cr}_2\text{O}_7$, washed, and dried.

White Discharge.—A thickening is prepared consisting of caustic soda and gum Seuegal. Stannous chloride is very gradually added whilst maintaining a low temperature. On the addition of sodium silicate and glycerin the discharge is ready for printing.

Yellow Discharge.—This may consist of the thickening described, with the addition of lead chloride, glycerin, and silicate of soda, or of plumbate and silicate of soda.

Indigo Blue Discharge.—Contains, besides the above white discharge, glucose and indigo, with a further quantity of caustic soda. Before printing, the pieces are prepared with glucose and dried on a cylinder.

Green Discharge.—A mixture of Indigo with the plumbate of soda yellow discharge.

In all cases after printing, the pieces are steamed for 1—2 minutes, then immediately fixed and washed. Fixing consists in treatment in four successive baths. The first and second contain silicate of soda, the first being twice the strength of the second. The remaining baths contain water only. The first three are kept boiling, the last is cold.

The yellow requires a further treatment with potassium bichromate and hydrochloric acid to develop the colour. Finally all are dried in the air, finished with gum Seuegal and Turkey red oil, and again dried.—R. B. B.

PATENTS.

Cloth and like Materials, Transferring from One Machine or Place to Another, in Bleaching, Dyeing, Finishing, and other Works, A New or Improved Apparatus for. J. Smith, Heywood. Eng. Pat. 7403, April 11, 1895.

AN apparatus for conveying cloth continuously from one machine to another during the process of finishing, &c.

It consists of two endless travelling aprons. One of these receives the cloth from one of the machines, the other is arranged above the first and is shorter. The cloth is transferred to the latter and then withdrawn in the open state by the second machine.

The cloth while upon the longer apron may be submitted to certain treatment, for example, dyeing, to effect which the apron is caused to pass through a dyebath.—E. B.

Rhea, Ramie, China Grass, and other Vegetable Fibres, and Undyed Fabrics Made from Vegetable Fibres, Improvements in the Mode of Bleaching. R. W. E. MacIvor and J. Chester, London. Eng. Pat. 10,424, May 27, 1895.

THE bark and resin or gum are first removed from the fibres, which are then thoroughly washed in hot water. Bleaching is accomplished by immersing the fibres, for a period not exceeding two hours, in a dilute solution of potassium or sodium permanganate, and then, for half an hour longer, in the same bath after the alkaline permanganate left in it has been decomposed by the addition of the requisite amount of hydrogen dioxide. Any manganese hydroxides retained by the fibres are removed by rinsing in dilute sodium bisulphite solution, and the fibres are thoroughly washed and dried.

The order of the principal operations as given above may be reversed, the hydrogen dioxide being first applied and then the alkaline permanganate.—E. B.

Bleaching Agents, Improvements in Electrolytic Decompositions, and especially in the Electrolytic Production of, and their Uses, and in Electrodes and Apparatus therefor. [Anode and Heating Bleaching Vat.] H. Blackman, New York, U.S.A. Eng. Pat. 11,016, June 4, 1895.

THE disadvantages attending the use of the weak solution of hypochlorite yielded by the electrolysis of brine, are overcome by heating the bleaching vat to a temperature of from 130° to 160° F. After passing through the bleaching vat, the solution is cooled and returned to the electrolytic cell, where it is re-electrolysed, and again passed into

the bleaching vat. The improved anodes are formed of conductive metallic oxides, preferably magnetite or ilmenite, which may be sawn into shape or fused with black slag and cast into the required form. The above process may be used in conjunction with the centrifugal electrolytic cell described in Eng. Pat. 19,170, 1892 (this Journal, 699, 1893).—G. H. R.

Yarn, Dyeing and Drying; Improved Process for. T. F. Hassler, Augsburg, Germany. Eng. Pat. 20,153, Oct. 25, 1895.

The yarn is wound on perforated, aluminium tubes closed at one end with valves, and terminated at the other with hollow, screw-threaded pins. The latter serve to attach the yarn tubes to a system of pipes contained in a frame. To dye the yarn the frame is lowered into a dye vat, and the liquors are drawn through the yarn by means of a pump. The drying is similarly effected by drawing hot air through the yarn, the frames, to this end, being placed in a heated chamber and attached to a fan.—E. B.

ERRATUM.

This Journal, 1896, 272, col. 1, line 17 from top. For "Cochineal" read "Cochineal."

VII.—ACIDS, ALKALIS, AND SALTS.

Nitroprussides, A New Method of Production. C. Marie and R. Marquis. Comptes rend. 1896, 122, 473.

Nitrous acid, set free by carbonic acid, reduces potassium ferriocyanide to ferrocyanide, and produces a small quantity of nitroprusside; acting on potassium ferriocyanide it produces nitroprusside, but the presence of alkaline carbonate prevents the completion of the reaction. If calcium ferriocyanide be employed, however, the whole of the ferriocyanide is changed.

This equation was verified by determinations of the calcium carbonate and hydrocyanic acid formed.—A. C. W.

Importation of Ammonia into United States. Board of Trade Journal, May 1896, 586.

A COMMUNICATION, dated April 16 last, has been received at the Foreign Office from Mr. A. G. Vansittart, Her Majesty's Consul at Chicago, stating that a considerable amount of ammonia is being imported by the packing houses established in Kansas City and throughout the west for freezing and cooling purposes.

It appears the demand exceeds the American supply. As these houses must keep a large stock in hand, one important firm in Kansas City has contracted for a whole year's import of ammonia to come from Berlin.

PATENTS.

Chlorides and other Salts, Improvements connected with their Electrolysis, and the Evaporation of Solutions. [Fuel Economy.] H. Tee, Liverpool. Eng. Pat. 6565A, March 30, 1895.

THE fuel is employed to raise steam for a high pressure engine which drives the dynamo. After use in the engine the steam which is still considerably above the atmospheric pressure, is conducted into covered salt pans, where it is condensed. The steam from the covered brine pans, which is at or near the atmospheric pressure, may be used in the low pressure part of the engine, or in a vacuum engine, from which it passes into a condenser, preferably formed of open brine pans. The same fuel is therefore used both for the electrolysis of sodium chloride, and for the production of common salt from brine.—G. H. R.

Chlorides and other Salts, Improvements connected with their Electrolysis, and the Evaporation of Brine and other Solutions. [Fuel Economy.] H. Tee, Liverpool. Eng. Pat. 6565, March 30, 1895.

ACCORDING to this invention the steam used in the engine employed for driving the dynamo for electrolytic purposes, is produced by evaporating brine in a covered vessel. If the steam be at or near the atmospheric pressure, the engine

will be a low pressure one. After use in the engine the steam is passed into pipes or chambers connected with open salt pans and condensed there, thus making the salt pans act as a condenser to the engine. The coal is therefore first used to generate steam and produce salt. The steam is utilised in the engine, and in condensing evaporates brine.—G. H. R.

Brine, Treating in the Manufacture of Salt, An Improved Method of and Apparatus for. J. Todd, Andreas, Isle of Man. Eng. Pat. 8342, April 27, 1895.

THE invention relates to economising the heat in the fire-gases as they leave the flues under an ordinary horizontal salt pan. A vertical boiler, egg-ended at the top, is set against the end of the salt pan farthest from the fireplace, through which one or more tubes (three are shown) pass, communicating with the furnace flue. The boiler is completely closed, and the tubes conveying the fire-gases issue through a plate in the top, into the chimney flue. This boiler is filled with brine through a valved pipe, its lower part being provided with a discharge valve for removing sediment; a tapped pipe from the boiler immediately over the salt pan permits discharge of the heated brine into the latter. It is stated that "owing to the peculiar construction of the boiler and to the fact that it is closed air-tight, the brine in it can be heated up above the temperature necessary to form crystals in an open pan, so that when the brine flows into the open salt pan the crystals will at once form."

Soluble Bodies, Envelope or Covering for Use in Preserving; An Improved. A. Le Chatelier, Paris, France. Eng. Pat. 7192, April 8, 1895.

See under I, page 341.

Alkaline Nitrates, the Decomposition of, Improvements in and in Apparatus for. H. K. Baynes and The Chemical and Electrolytic Syndicate, Limited, London. Eng. Pat. 7273, April 9, 1895.

A MIXTURE of an alkaline nitrate with about 2 parts of ferric oxide is delivered gradually into a slowly revolving, slightly inclined retort, by means of a hopper and archimedian screw. The retort, except as to its ends, is heated by a furnace, and is provided with longitudinal ribs internally, to keep the particles of the charge in motion; and their adherence to the sides is prevented by the blows of hammers on the sides of the retort effected automatically by "wipers," acting on the hammers fixed externally, and controlled by springs. Air, or steam and air, is passed into the retort at its lower end (where also is the outlet for the mixture as it is worked off), and the nitrous fumes have exit, either through the hollow archimedian screw or through a specially-provided passage, into suitable apparatus for transformation into nitric acid. The fixed product of the process, an alkaline ferrite, is lixiviated, to obtain caustic alkali and ferric oxide for re-use.—E. S.

Nitric Acid and the Recovery of By-products, Treating Nitrates for the Production of, Improvements in. R. Main, Stevenston, and W. Donald, Saltcoats, Ayrshire. Eng. Pat. 23,819, Dec. 12, 1895.

A MIXTURE of sodium nitrate and manganic oxide is heated in a muffle furnace, and the nitrogen oxides evolved are taken to an oxidising tower, charged with nitric acid and water. The nitric acid recovered may be distilled with sulphuric acid to obtain strong nitric acid, and the dilute sulphuric acid remaining may be concentrated, the vapour from it being returned to the tower. The furnace product, consisting of soda and manganous oxide, is treated with water, steam, and a current of air, to obtain caustic soda and to regenerate manganic oxide for re-use.—E. S.

Zinc, Chloride of, and other Metal Chlorides, Improvements in the Manufacture of, applicable also to the Manufacture of Acetate or Sulphate of Zinc. C. Hoefner, Giessen, Germany. Eng. Pat. 7560, April 13, 1895.

To obtain zinc chloride, blende is treated with nitric acid, either mixed with hydrochloric acid, or with sodium chloride and sulphuric acid, under conditions to set free the sulphur

without oxidising it, and so as to liberate nitric oxide (easy to regenerate as nitric acid) as is represented by the equation—

Sodium sulphate, if present in the solution, may be separated by freezing. If the solution, after purification, be used to obtain chlorine and zinc by electrolysis, the residual solution is again used in the treatment of zinc ores. Zinc sulphate is obtained from blende by treatment with nitric and sulphuric acids. Ferric chloride may be obtained from sulphide ores by the first described process, and its solution be utilised as a solvent of zinc from roasted zinc ores.

Equations are also given, representing the processes for obtaining nickel sulphate, cupric chloride, and lead acetate from the respective sulphides.—E. S.

Cyanides, Improvements in the Manufacture of. H. W. Crowther, West Bromwich, E. C. Rossiter, and G. S. Albright, Birmingham. Eng. Pat. 8669, May 1, 1895.

THE inventors have found that the process and apparatus for drying potassium or sodium sulphocyanide described in Eng. Pat. 8305, 1894 (this Journal, 1895, 656) are adaptable for transforming such sulphocyanides into cyanides by heating them with zinc or lead.—E. S.

Nitrogen, Fixation of, and the Production of Cyanides, Improvements in the. T. Twynam, Egham, Surrey. Eng. Pat. 9332, May 11, 1895.

LUMES of coke saturated with potassium or sodium carbonate are exposed in a basic-lined chamber or shaft to a current of the waste gases passing off from a Bessemer converter, between the commencement of the carbon period and the drop of the flame; though, in basic steel making, the gases may pass until about the middle of the afterblow. The cyanide formed may be washed out of the coke; or it may be made to yield ammonia by passing air and steam after the hot furnace gases.—E. S.

Sulphocyanides, Manufacture of from Nitrites, Bisulphide of Carbon, and Sulphuretted Hydrogen. O. Imray, London. From Goerlich and Wichmann, Hamburg, Germany. Eng. Pat. 11,287, June 8, 1895.

A NITRITE, potassium nitrite for instance, carbon bisulphide, and hydrogen sulphide are heated together in a closed vessel provided with an agitator and pressure gauge, to about 120° C. to obtain potassium sulphocyanide, sulphur being separated. The proportions used are indicated by the equation—

The nitrite is added in aqueous solution into which the H_2S has been passed; or the latter may be forced into the digester.—E. S.

Cyanogen Compounds, Improvements in the Manufacture or Production of. A. von Rad and J. Rosenfels, Pforse-Augsburg, Bavaria. Eng. Pat. 1022, Jan. 15, 1896.

BARIUM or calcium carbide, heated to redness in a current of nitrogen, yields a cyanide. It is preferred, however, to employ a mixture of the carbide with a dry alkaline carbonate in equivalent proportion. The following equations show the reactions believed to take place:—

1. $\text{CaC}_2 + \text{K}_2\text{CO}_3 = \text{K}_2\text{C}_2 + \text{CaO} + \text{CO}_2$, and
2. $\text{K}_2\text{C}_2 + \text{N}_2 = 2\text{K}(\text{NC})$.

If ammonia gas, instead of nitrogen, be passed over the mixture at a red heat the cyanide is formed as before, and hydrogen is set free.

In the manufacture of potassium ferrocyanide from potassium carbonate and nitrogenous animal matters, barium or calcium carbide is incorporated with the mixture instead of carbon, with, it is stated, great advantage.—E. S.

Chloride of Lead, for Use in Electrical Storage Batteries, and for other Purposes, Improvements in the Preparation of. A. R. Davis, Manchester. Eng. Pat. 8914, May 4, 1895.

LEAD oxide is treated in a steam-jacketed vessel (preferably made of enamelled iron) with dilute hydrochloric acid,

and when the hot solution is saturated, it is run into a series of coolers, in which about three-fourths of the lead chloride crystallises out. The solution overflows into a well, from which, when cold, it is raised to an elevated steam-jacketed vessel, to be strengthened by addition of more acid, and, when hot, is run into the first-named vessel, provided with an agitator, in which the liquor is again saturated with lead oxide, the process being thus made continuous. As the volume of liquid continually increases, portions of the cooled mother-liquor are periodically withdrawn, to be precipitated by lime or soda, the lead oxide thrown down being utilised in the dissolving vessel. Acetic or nitric acid may be added to the hydrochloric acid used.—E. S.

Chlorine and Alkalies or Alkaline Earths, Treating Chlorides for the Production of, and the Recovery of By-Products, Improvements in. R. Main, Stevenston, and W. Donald, Saltcoats, Ayrshire. Eng. Pat. 10,713, May 30, 1895.

A MIXTURE of sodium chloride with manganic oxide is heated with nitric acid, slightly diluted, and the chlorine evolved is collected. The remaining mixture of nitrates with free nitric acid, is evaporated and roasted, and the nitrogen oxides that come off are oxidised to nitric acid by suitable means. The residue is heated with water, and air is blown in to peroxidise the manganese oxides, from which the caustic soda solution is separated, and may be dried up as such or converted into carbonate. Potassium, barium, calcium, magnesium, or other chloride may be substituted for sodium chloride in the process; but if, as in the case of magnesium chloride, the hydrate be not soluble, the residue left after expelling nitrogen oxides is exposed in shallow trays to the action of heated air, to regenerate the manganic oxide. The product may be digested with ammonium chloride, and then with nitric acid, to obtain chlorine.—E. S.

Decomposing Sulphuretted Hydrogen, and Obtaining Ammonia, Compounds of Ammonia, Oxy-sulphides, Sulphides, and Sulphur, Process for. O. Imray, London. From Goerlich and Wichmann, Hamburg, Germany. Eng. Pat. 10,931, June 1, 1895.

HYDROGEN sulphide is passed through a solution of a nitrite, as sodium nitrite for instance, when one or other of the following reactions ensue, according to the proportion of the gas:—

1. $\text{NaNO}_2 + 3\text{H}_2\text{S} = \text{NaOH} + \text{NH}_3 + \text{S}_3 + \text{H}_2\text{O}.$
2. $\text{NaNO}_2 + 5\text{H}_2\text{S} = \text{NaSH} + \text{NH}_4\text{SH} + \text{S}_3 + 2\text{H}_2\text{O}.$

Part of the sulphur dissolves in the alkaline solution, producing an oxy-sulphide.

A mixture of carbon bisulphide and ammonia, heated with a nitrite in a closed vessel, is decomposed with separation of sulphur. Gases or liquids containing hydrogen sulphide may be freed from it by treatment with a nitrite.—E. S.

Acetic Acid, An Improved Process of Obtaining from Pyroigneous Salts. W. P. Thompson, London. From Dr. C. von der Linde, Crefeld, Germany. Eng. Pat. 3987, Feb. 21, 1896.

THE crude pyrolignite (sodium pyrolignite for instance) is thoroughly decomposed by sulphuric or hydrochloric acid, and the acetic acid released is distilled *in vacuo*, in order that it may be obtained free from any tar-spirit or oils contained in the pyrolignite.—E. S.

VIII.—GLASS, POTTERY, ENAMELS.

Glass, the Function of Alumina in the Composition of. L. Appert. Bull. de la Soc. d'Encouragement, 1896, 1, [3] 415—416

RESEARCHES on the composition of ancient glass have led the author to certain practical conclusions respecting the influence of alumina when used in the manufacture of glass. It appears that the introduction of alumina impedes, if it does not prevent, the tendency of glass to become devitrified by frequent changes of temperature and besides its

presence admits of the substitution, in equivalent proportions, of lime for soda or potash, the glass thus modified being more solid, more elastic, and less alterable. Alumina substituted for silica in glass in not greater proportion than 7 to 8 per cent. slightly increases its fusibility, its malleability not being sensibly diminished. One inconvenience, however, attends the introduction of alumina into colourless glass; namely, that it tends to give colour owing to its action on any iron oxide present; hence the materials used should be selected of as great purity as possible. The alumina is best introduced as a pure clay, or as felspar. The author sums up by stating that the use of alumina in bottle glass, admits of the introduction of a good proportion of earthy bases; and that its presence is advantageous even in the choicer varieties of glass.—E. S.

Hungarian Stone Ware. Sprechsaal, 1896, 28, 2.

HUNGARIAN makers lacking a plastic clay suitable for the preparation of feldspathic ware made in the English manner have had recourse to the use of as much as 50 per cent. of lime. Stoneware made from such a mixture and burnt at a temperature corresponding with the fusing point of Seger's cones 07—08, is very sensitive to slight differences of temperature in burning, becoming yellow when slightly overburnt, and taking the glaze badly when under-burnt. Ordinary German stoneware glazes and glazes containing boric acid, are unsuitable for this class of goods. Some improvement in the ware may be effected by the addition of kaolin, and, as a glaze, a mixture is used containing 36 parts by weight of litharge, 25 of sand, 18 of felspar, seven of carbonate of potash, seven of salt, and seven of broken glass. This mixture is fused and finely ground, with the addition of a few per cents. of litharge; the composition of the glaze corresponds to the formula—

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Wood, Strength of, Wet and Dry. J. Marebott, Mitt. k.k. Techn. Gewerbe-Museums (Vienna), 1896, 82—89.

THE author has determined certain mechanical constants of two species of beech, Weissbuche (*Carpinus betulus* L.) and Schwarzbuche (*Ostrya carpinifolia* Scot.) in a moderately dry and in an approximately saturated condition and has arrived at the following conclusions.—(1.) The compressive strength of the wet wood is about 55—60 per cent. smaller than that of the dry and the resistance to bending stress is about 10 per cent. smaller. (2.) The modulus of elasticity of the wood is somewhat increased by saturation with water. (3.) In bending tests, the elastic limit and the ultimate strength are nearly coincident in the case of the saturated wood, there being no intermediate condition of flow. (4.) The work done in the bending test of the saturated wood is about 60 per cent. smaller than in that of the dry.—B. B.

Sand Cement. B. H. Wallin. Thonind Zeit. 1896, 20, 18.

SO-CALLED sand cement consists of Portland cement intimately ground with sand. Three grades are put on the market containing respectively 1 part of cement to 3, 8, and 12 parts of sand. The author has made experiments on the tensile and compressive strength of cement mortars made by mixing these sand-cements with further quantities of sand, the proportions being adjusted to give ultimately 1 part of cement to 25 of sand. The mixture prepared in this manner from the 1:3 sand cement had a tensile strength at 28 days of 7.23 kilos. per sq. centimetre and a compressive strength at the same date of 38.2 kilos. The sand cements having larger proportions of sand, when made into cement mortar so that the final mixture contained the same proportion of cement and sand as that made from the richest sand cement, gave lower results. Any increase in the proportion beyond 25:1 yielded mixtures considerably weaker than those already mentioned.—B. B.

Portland Cement, Hardening of, in Sea Water. R. Bech. Thonind. Zeit. 1896, 20, 32.

THE author has carried out a series of experiments in which test pieces of cement were placed in cages and exposed to sea water constantly renewed by natural flow. One set of tests was made with the cage sunk 1 metre below the level of the water, while in the other it was at the surface of the water, and was exposed or covered according to natural fluctuations. Briquettes of 1 part of cement to 1 part of sand thus exposed gave irregular results, which were on the whole lower than those obtained in fresh water. Briquettes kept on the surface of the water gave results similar to those of the immersed briquettes during the first year, but fell somewhat behind in the second year, a result probably due to mechanical attrition. The usual action of the magnesium salts in the sea water upon the lime compounds of the cement was also observed.—B. B.

PATENTS.

Slag Cements, Improvements in the Manufacture of. S. Jørgensen, Copenhagen, Denmark. Eng. Pat. 9210, May 9, 1895.

ORDINARY slag cement, consisting of a mixture of slag and slaked lime, has its setting time diminished and its strength improved, by admixture with it of a material obtained by slightly igniting a portion of the same mixture. The incorporation of the two materials should be intimate and is preferably effected in "tube mills."—B. B.

Gypsum Pulverised, and other Finely Divided Materials, Apparatus for Drying or Dehydrating, Improvements in and Connected with. H. Kropff, Dusseldorf, Germany. Eng. Pat. 6868, April 3, 1895.

THE apparatus consists of a vertical cylindrical case containing horizontal shelves, provided with stirrers driven by means of radial arms from a vertical shaft co-axial with the cylinder. The material to be dried is fed into a hopper at the upper end of the apparatus, and is passed systematically from shelf to shelf, being heated during this process by steam, circulating also in a systematic manner from the lower to the upper part of the cylinder. Water vapour and dust are drawn off from the top of the cylinder and are caught in a separate drum. The material dried by passage down the cylinder is ejected through openings in the bottom of the casing.—B. B.

Kilns or Furnaces Applicable for Burning Lime and other Materials; Improvements in. H. Simmonds, Colne, and J. Delaney, Horton. Eng. Pat. 7425, April 11, 1895.

THE kiln patented is designed to burn limestone or similar material with gaseous fuel with or without a supplementary supply of solid fuel. It consists of a vertical shaft, the upper part of which contains the material to be burnt while the lower serves as a cooling chamber. An arch divides the two portions, but does not completely cut off access from the upper to the lower. Gas from a producer set at the side of the kiln, enters under this arch and burns there, the flame heating the materials stacked above the arch. The secondary air-supply of the producer is heated by passage through sinuous flues set in the lower part or cooling chamber. An inlet in the side of the kiln opposite the flue admitting the producer gas, allows of the introduction of a subsidiary supply of solid fuel at a point immediately below the bridge. The charging of the kiln is effected through an automatic tipping door at the top.

—B. B.

Cement or Plaster Compounds, Improvements in the Manufacture of. F. W. Golby, London. Eng. Pat. 21,293, November 9, 1895. From F. Schmeisser, Leipzig, Germany.

THE composition patented, consists of about 50 kilos. of plaster and 5 kilos. of cocoanut fibre; sand may be added. The material may be moulded and used for making or repairing floors, roofs and similar portions of a structure.—B. B.

Moisture, Nitre or Acids in or Upon Walls or other like Surfaces, A New or Improved Composition for Preventing the Formation or Accumulation of, said Composition being Capable of being made into Artificial Stones or Bricks for Building Purposes. F. Ludewig, Düsseldorf, Germany. Eng. Pat. 23,981, December 14, 1895.

A COMPOSITION designed for the purposes mentioned in the heading, is made by mixing such substances as powdered charcoal, cement, lime, kieselguhr and peat. Various proportions may be used.—B. B.

X.—METALLURGY.

Pig Iron, Containing very little Phosphorus, Production of. N. Tholander. Oesterr. Zeits. Berg. u. Hüttenw. 1896, 54, 20.

CHARCOAL iron, on account of the very small proportion of phosphorus contained in it, commands a high price, and is largely exported from Sweden. In the production of "grey" charcoal-iron, practically the whole of the phosphorus contained in the ore, limestone, and charcoal employed, passes into the metal; and very little can be done towards its elimination. The main point lies in the choice of suitable and rich ore, as free as possible from phosphorus, and requiring a minimum of fuel and limestone for its reduction. The amount of phosphorus derived from the fuel varies somewhat, but averages (when 50 per cent. of fuel is used) 0.015 per cent. calculated on the iron. In any case the bark of trees is richest in phosphorus; it might be advisable, therefore, to use only such charcoal as has been stored for some time in a dry situation, carefully sifted, and prepared from wood denuded of its bark.—H. T. P.

Lead Slags, as flowing from Furnace, Temperature of. M. W. Iles. School of Mines Quarterly, 17, 20—25.

THE method of taking the temperature, was to place a steel bar of from one to two pounds weight in the flowing slag, and when hot to withdraw it, plunge it and any adherent slag into a weighed quantity of water, and note the rise in temperature. It was noticed that the larger the amount of slag adhering to the steel, the lower was the result, which seemed to indicate that the figure taken for the specific heat of the slag was too high. Furthermore a lower result was obtained, when the steel bar was heavier, thus, a piece of steel weighing 1.07 lb. gave a resulting temperature of 2,170° F., whereas another piece weighing 1.875 lb. indicated 1,641° F., or a difference of 529°. This is at present inexplicable. The averages of the temperatures obtained with two separate furnaces were 1,878° and 1,642° F.

—A. W.

Gases from Lead Furnaces, Temperature of. M. W. Iles. School of Mines Quarterly, 17, 19—20.

TESTS of the temperature of exit gases from two blast furnaces smelting silver, lead, and gold ores, working as far as possible under exactly the same conditions and both possessing the same amount of accretions of sulphides of zinc and lead upon the side walls, showed an average temperature for 28 days of 214° F. The temperature of the gases increased as the wall accretions increased. A standard dial pyrometer and a Siemens copper ball pyrometer were used so as to check one another and the averages of the results obtained with each were nearly identical.—A. W.

Pig Iron, Sulphur in, Drown's Method of Determining. G. Auchy. J. Amer. Chem. Soc. 18, [4], 405.

PATENTS.

Pulverised Ore and Other Substances, Improved Apparatus for Roasting. Paul Naef, Argentine, Kansas, U.S.A. Eng. Pat. 2736, Feb. 7, 1895.

A ROTATING inclined iron cylinder lined with firebrick or other refractory material, is connected at the upper end with a fixed chimney, and closed at the lower end by a plate, through the centre of which a tube passes into the interior, and is surrounded by a larger tube, closed at the top, but having apertures at the lower end, so that the air passes along the inner tube and back through the outer tube on its way to the inside of the cylinder. The cylinder is divided longitudinally into chambers by iron partitions, having apertures to allow the ore to pass from one chamber to another, as the cylinder revolves. Neither the tubes, nor the partitions extend into the upper part of the cylinder, which, however, is furnished with longitudinal ridges. The feeding hopper is at the upper end, whilst the discharge is effected through apertures in the bottom plate, fitted with spring valves, which in course of the revolution are released by fixed cams, and thus the apertures are temporarily opened.—D. A. L.

Reverberatory Furnaces used for Metallurgical Purposes, Improvements applicable to. John Spencer, Conthridge, Lanarkshire. Eng. Pat. 8848, May 4, 1895.

A FUEL chamber forms part of the same structure as the reverberatory furnace, the communication between them being below an adjustable hanging bridge, and brick chequer work is arranged in the communicating passage. Coal is charged into the fuel chamber up to or above the bottom of the hanging bridge, and air for combustion is introduced under pressure into a perforated box at the lower part of the fuel chamber, opposite the bridge, and having to pass through the fuel. Air may also be introduced from the top of the structure into the communicating passage to complete the combustion of the gases. By preference the air is pre-heated by the waste gases from the reverberatory or otherwise.—D. A. L.

Iron and Steel, Manufacture of, Improvements in, by which Sulphur is eliminated. Henry Clement S. Dyer, Elswick Works, Newcastle-on-Tyne. Eng. Pat. 9081, May 7, 1895.

THE presence of manganese being ensured, the ordinary process of making iron and steel is interrupted, by allowing the molten pig iron to cool to a temperature, at which sulphur combines more readily with manganese than with iron. At the blast furnace this takes place before running on to the pig bed, and in the Bessemer process, before charging into the converter, whilst in the open hearth it is effected by turning off the gas, and may be accelerated by adding cold metal. In any case time enough must be given for the combination and removal of the sulphur, and to this end arrangements to retain the metal at the required temperature are mentioned.—D. A. L.

Iron, Case-Hardening; Improved thin Liquid Substance for. William Phillips Thompson, Liverpool. From Hans Schaaf, Charlottenburg, Germany. Eng. Pat. 9610, May 15, 1895.

THE mixture consists of the following substances and is preferably prepared in the following manner, though the proportions may be varied. 200 grms. of potassium ferrocyanide and 40 grms. of powdered chalk are stirred together, whilst a mixture of 100 grms. of water-glass and 75 to 100 grms. of water is gradually added; more water-glass is next stirred in until the mixture has become gelatinous; it is then rendered permanently thin by the addition of ammonia. Articles are brushed over well with the mixture, warmed, re-brushed, and finally heated in a coal or charcoal furnace.

—D. A. L.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Persulphuric Acid, the Formation of. K. Elbs and O. Schönherr. *Zeits. f. Elektrochem.* 2, 245—252.

FAIRLY strong solutions of persulphuric acid have been prepared, as suggested in a former communication (this Journal, 1895, 583 and 1896, 277). A cylinder 14 cm. high and 7 cm. diameter, containing a porous cell which nearly filled it, had a stopper through which were sealed the electrodes (a large slit hollow cylinder in the porous cell as cathode, and a wire of about 2.5 sq. cm. surface, bent in a ring round the middle of the cell, as anode), and which was also provided with a gas delivery tube. The cell, nearly filled, contained 110 c.c. of sulphuric acid of 400 grms. H_2SO_4 per litre, and the outer space 70 c.c. of acid of 500 grms. H_2SO_4 per litre. The anode was red-heated just before beginning, the whole plunged in broken ice, and a current varying from 3 to 2 ampères passed for 13 hours, a copper voltameter being continually in circuit, and a water voltameter connected so as to be brought into circuit at will. The yield of persulphuric acid (58 c.c., containing 129 grms. H_2SO_4 and 510 grms. $\text{H}_2\text{S}_2\text{O}_8$ per litre), amounted to 29.6 per cent. of that corresponding to the electricity which had passed. 40 c.c. of the anode fluid, precipitated by barium carbonate and filtered, gave a fluid free from hydrogen peroxide, barium, or sulphuric acid, containing 519 grms. $\text{H}_2\text{S}_2\text{O}_8$ per litre.

Portions of different concentrations kept and analysed from time to time, showed that pure solutions are fairly stable, but that as the amount of free sulphuric acid present increases, so does rapidly the rate of decomposition of persulphuric acid. As might have been expected, dilute solutions, even when sulphuric acid is present, are more stable than strong solutions. Rise of temperature quickens the rate of decomposition, but the last portions of persulphuric acid are very stable, even when boiled in acid solution with oxalic acid.

The presence of such sulphates, as those of ammonium, nickel, potassium, or aluminium, exerts great influence in increasing the yield of persulphuric acid formed by electrolysis in a given time. Other sulphates are found to act similarly, though to different extents. Some average figures are given in another table. The much greater influence of potassium than of sodium sulphate is remarkable. Aluminium sulphate is very active even in very small amounts.

The condition of the electrodes affects the yield. They should be freshly heated to redness before each experiment. The authors have not been able to discover the precise way in which this heating acts, but it seems that a smooth electrode is better than a rough one, for platinising the anode reduced its activity, whilst on again heating the platinised anode to redness, and especially on red-heating after dissolving off the deposited platinum by aqua regia, its activity was restored. The anode should be arranged horizontally, that the persulphuric acid formed may not remain in contact with it and be itself electrolysed.

Ammonium sulphate is the most suitable salt to use, as it is more soluble than the potassium or the aluminium salt; more especially too, as the aluminium persulphate when formed cannot be crystallised. The normal sulphate is used, in saturated solution, and on filtering from the separated persulphate, the solution should be neutralised with ammonium carbonate before saturating again with ammonium sulphate.

Schoop has stated that lead persulphate is precipitated on adding lead acetate to ammonium persulphate, and draws therefrom support for Darrieus' hypothesis of the chemical actions in storage cells. This is erroneous, as pure ammonium persulphate gives no precipitate with lead acetate; Schoop's precipitate was simply lead sulphate. The authors have before shown that Darrieus' hypothesis, as far as it is based on the behaviour of persulphuric acid, is untenable.—J. T. D.

Persulphuric Acid, Formation of, in Storage Cells. Paul Schoop. *Zeits. f. Elektrochem.* 2, 272—275.

ELBS and SCHÖNHERR (this Journal, 1896, 277), state that: 1. No persulphuric acid is formed when sulphuric acid of

such strength as is used in storage cells is electrolysed with such current densities as occur there; 2. Persulphuric acid in dilute sulphuric acid solution has no oxidising action on lead oxide, and hence cannot be operative in storage cells; 3. The precipitate which the author obtained by acting on lead acetate with potassium persulphate was simply lead sulphate, and contained no lead persulphate.

To overthrow Darrieus' hypothesis it would, in the author's opinion, be necessary to show, not only that persulphuric acid does not remain in quantity after the action in the cell has stopped, but that it is not continuously formed and decomposed during the action, leaving only traces at the end.—J. T. D.

Bleaching Agents, Improvements in Electrolytic Decompositions, and especially in the Electrolytic Production of, and their Uses, and in Electrodes and Apparatus therefor. [Anode and Heating-Bleaching Vat.] H. Blackman, New York, U.S.A. Eng. Pat. 11,016, June 4, 1895.

PATENTS.

Secondary Batteries, Electrode Plates or, Process for the Production of. C. Lucknow, Deutz, near Cologne, Germany. Eng. Pat. 5205, March 12, 1895.

THE inventor follows the methods of Planté in forming his electrodes by electrolysis. He prefers "strongly diluted" electrolytes for obtaining a maximum degree of oxidation, his "treatment being distinguished by the application of strongly diluted, slightly acid, neutral or weak alkaline solutions of fixed percentages" ["The most suitable fixed percentages of salt amount, according to the kinds of salt, to from 1 to 3 per cent. of the anhydrous salts; and the quantity of the free acids or caustic alkali must not exceed 1.5 per cent. of the solution. The use of such strongly diluted electrolytes forms solely the characteristic feature of the invention"]. As salts employed as electrolytes, are used:

"a. The salts of all the light metals (*i.e.*, of those metals whose oxides are heavier than the elements themselves) and of ammonium, during the decomposition of which by the electric current no products of decomposition appear at the + pole, which have a retarding effect on the oxidation of the metallic lead."

"b. The double salts or salt mixtures of the light metals and of ammonium with each other and having the above-named qualities."

"c. The salts of the heavy metals (*i.e.*, those metals, the oxides of which are lighter than the elements themselves), their double salts or salt mixtures with each other, or with the light metals and the ammonium, the above-named qualities being taken for granted, and in which a separation of the metal at the - pole either does not take place at all or may be prevented by a slight quantity of free acid."

—J. C. R.

Chlorides and other Salts, Improvements connected with their Electrolysis and the Evaporation of Solutions [Fuel Economy]. H. Tee, Liverpool. Eng. Pat. 6565A also 6566, March 30, 1895.

See under VII., page 356.

Electric Batteries, Improvements in or connected with [Carbon Positive]. C. P. Shrewsbury, F. L. Marshall, J. Cooper, London, and J. L. Dobell, Modbury. Eng. Pat. 8306, April 26, 1895.

THE improvement consists in enclosing the carbon electrode in a porous cell which is suspended from the lid or cover of the battery, the cell being large enough to allow of the free circulation of the fused nitrate. It is claimed that

this arrangement facilitates the combination of the oxygen of the fused salt with the carbon electrode, and that the carbon dioxide produced readily escapes at the top of the cell in a pure state. The negative element is formed of iron or other suitable material.—G. H. R.

Electric Batteries, Improvements in or connected with [Carbon Positive]. C. P. Shrewsbury, F. L. Marshall, J. Cooper, London, and J. L. Dobell, Modbury. Eng. Pat. 8876, May 4, 1895.

THE object of this invention is to simplify and improve the construction of the battery described in a previous patent (Eng. Pat. 12,483, June 27, 1894; this Journal, 1895, 974). The battery consists of an oblong rectangular trough, of iron, divided by transverse plates of the same material, which extend to a height below the level of the fused nitrate. These divisions are in electrical connection with the iron trough, and form with it the negative electrode. The positive electrodes are carbon plates, which are enclosed in porous jars which pass through the lid of the battery, and are suspended from it by flanges formed on them. A rim surrounds each opening in the cover, and fixed upon, and in electrical contact with the upper end of each carbon plate, is a corresponding cover which fits upon the rim surrounding the slot. Surrounding the entire group of the carbon plates and their covers is another rim, thus forming round each opening a channel which is filled with a suitable alloy of low melting point. This alloy is kept fused by the heat of the cell, and maintains electrical connection between the positive plates while sealing the cover. An inclined circulation pipe connects the opposite ends of the cell, and the fused nitrate enters this pipe at the lower end, and passes through it to the upper end, which is provided with a perforated arm contained in a recess in the side of the cell. At the opposite end of the cell is a vaporising chamber, which is wholly or partially immersed in the fused nitrate which maintains it at the required temperature. A reservoir containing nitric acid is placed above the vaporiser, and connected with it by a pipe and suitable valve, so that the supply of acid can be regulated. A pipe provided with a back pressure valve connects the vaporiser with an injector placed near the lower opening of the circulation pipe, so that the acid fumes produced in the vaporiser are injected into the spent nitrate and regenerated.—G. H. R.

Electric Batteries, Secondary, Electrodes for, A New or Improved Method of Manufacturing. H. Leitner, Niederschönhausen, near Berlin, Germany. Eng. Pat. 780, Jan. 11, 1896.

ELECTRODES are manufactured by intimately mixing oxide of lead (95) with retort-carbon (5) and glycerin (25 parts). The pulpy mixture (which becomes hot) is moulded to the desired shape and sets to a more brittle mass. It is reduced electro-chemically to porous lead, which is pressed and bent into flat, curved, or cylindrical shape.—J. C. R.

Voltaic Batteries [Secondary], Improvements in. D. G. Fitzgerald and W. C. Bersey, London. Eng. Pat. 1054, Jan. 15, 1896.

THE object is to construct a "dry" (electrolyte) or absorbent battery of low resistance. The absorbent mixtures preferred are compounded as follows:—

	Parts by Weight.
I. Sulphate of zinc (commercial).....	30
Yellow prussiate of potash.....	26
Granulated pumice or Tripoli stone.....	100
11. Sulphate of iron (commercial)	22
Yellow prussiate of potash.....	20
Pumice or Tripoli stone (granulated).....	100

The absorbent material or mixture of materials is packed in the cell around the plates and saturated with sulphuric acid.

"The sulphuric acid thus added, is of a strength such that the resulting liquid electrolyte will correspond to acid of a density of about 1·300, at which strength of the acid persulphuric acid is not generated."—J. C. R.

Organic Compounds, Improvements in the Reduction of. C. Kellaer, Vienna, Austria. Eng. Pat. 3090, Feb. 11, 1896.

THE inventor claims a process for the reduction of organic compounds (in neutral, alkaline, or acid solution) by intimate contact with an amalgam of an alkaline metal that has been produced by electrolysis in a chamber separate from the reducing chamber. "The reduction process is not limited in its application to a determined class of substances, but can be applied in all cases of reduction where nascent hydrogen can be advantageously used as a reducing agent. Thus the process can be employed for the reduction of nitrobenzene, nitrotoluene, and in general of the nitro derivatives of aromatic hydrocarbons or of the carbon sulpho-acids, and also for the direct production of azo compounds and hydrazo compounds, by reduction of the corresponding nitro substances in alkaline solution. Similarly the reduction of compounds, such as "sugar acid," belonging to the group of carbon hydrates, can be effected in acid solution by means of the process."—J. C. R.

(B).—ELECTRO-METALLURGY.

Silver, Möbius's Electrolytic Method for Refining. G. Faunce. Oesterr. Zeits. für Berg. und Hüttenw. 1896, 44, 30.

THE process described, is in successful operation at the works of the Pennsylvania Lead Company and elsewhere.

The silver to be refined is first treated by ordinary well-known metallurgical processes to reduce the quantity of other metals present (lead, copper, bismuth, &c.) to at most 2 per cent. It is then cast in sheets measuring 45 × 25 × 1·3 cm. and weighing 13—15 kilos. each. These serve as anodes. The cathodes are formed of thin, rolled sheets of pure silver, 33 × 55 × 2 cm. in size. The electrolyte is a solution of the nitrates of copper and silver, to which 0·5—1 per cent. of nitric acid is added to prevent the deposition of the copper. Four cathodes and three anodes are placed in each cell at distances apart severally of 43 mm.

The anodes are enclosed in muslin bags for the purpose of intercepting the undissolved matters which fall from them as the action proceeds. These consist of gold, bismuth, the principal portion of the lead (in the form of dioxide), and a little silver and copper.

A sheet of woollen cloth stretched on a frame near the bottom of each cell, catches the silver as it is removed from the cathodes by a mechanically-moved wooden scraper.

The intensity of the current employed is 18 amperes per square foot of cathode surface.

The silver is collected from each cell at intervals of two days, the gold once a week. The silver is washed with water and then melted in graphite retorts capable of holding 560 kilos. each, and is thus obtained of a fineness of 999—999·5.

The residue of gold, &c., after being melted, granulated, and treated with acid, gives gold of a fineness of 996—998.

To the above process, care must be taken that the amount of copper in the electrolyte does not exceed 4—5 per cent., as otherwise the silver is not obtained in a pure state.

—E. B.

Magnesium, Electrolytic Preparation of. F. Oettel. Zeits. Elektrotechn. 1895, 2, 394.

IN the electrolytic preparation of magnesium the difficulty hitherto has been due to the fact that the metal is not obtained in compact masses but in small spheres which cannot readily be made to unite. This is, no doubt, due to a thin coat of magnesia on the surface of the metal, which is attributed partly to an impurity of magnesium sulphate in the carboallite used as raw material and partly to the presence of aqueous vapour. It is therefore necessary to remove the impurities and to protect the melt from contact with aqueous vapour. A trace of magnesia still present after purification can be rendered harmless by the addition of fluorspar.

The author also describes an apparatus for the preparation of magnesium on a small scale in the laboratory.

—A. K. M.

Galena containing Zinc, The Working of. W. Borchers. Zeits. f. Elektrochem. 2, 277—278.

For some time chemists have sought a method of treating the galenas of Colorado and New South Wales, which contain silver and zinc. The mechanical preparation of the ores has been improved, and the loss of metal in this way lessened, but hitherto no way of utilising the zinc has been devised.

In 1893 the author pointed out that any successful method must proceed, after appropriate mechanical treatment, somewhat on the following lines:—1. Roasting in the air at a low temperature. 2. Completion of the conversion of the zinc into sulphate by treating the mass with sulphuric acid, or sulphur dioxide and air. 3. Lixivation, to extract the zinc sulphate. 4. Working up the solution for zinc sulphate, or by electrolysis for metallic zinc. 5. Smelting the residue for crude lead. 6. Desilverisation. Precisely this process has been worked out by the Broken Hill Company. Siemens Brothers and Co. have undertaken to deposit the zinc from the sulphate solution at a cost of 72s. per ton, making the cost, with the royalty, 92s. per ton. Another way of dealing with the zinc solution is to precipitate it by magnesia.—J. T. D.

Antimony, Electrolytic; A New Commercial Product. Zeits. Elektrochem. 1896, 2, 524—525.

ELECTRO-DEPOSITED antimony is now beginning to appear in the market in very brittle grey plates, 2 mm. in thickness, with the striated or modular surface at the back, which is characteristic of metals so obtained, but on the other side it is smooth, lustrous, and, in places, silver white. The fracture is white and crystalline, and the depositing bath is a solution of a sulphantimonite. Analyses of the deposit before and after fusion, are as follows:—

	Unfused.	Fused to Regulus
	Per Cent.	Per Cent.
Iron	0.008	0.0046
Lead and copper	Trace	0.004
Sodium	0.014	..
Arsenic
Sulphur	0.288	0.001
Antimony	99.690	99.984

—W. G. M.

Metals, Electro-Deposition of; by Alternating Currents. B. Rösing. Zeits. f. Elektrochem. 2, [25], 550—552.

It is known that metals can be deposited from solutions by alternating currents, but no practical application has been made of this, because the amount of metal deposited is small in comparison with the energy expended. This disadvantage can be partly removed by using highly asymmetrical alternating currents. Such currents can be obtained by sending a continuous current through a commutator provided with adjustable brushes, so that the current which issues shall flow in one direction for a definite time *f*, and in the opposite direction for a much shorter time *d*. The author's experiments are comparative. One-half of a constant current is sent directly through an electrolytic cell (the comparison cell); the other half is sent through the above commutator and a similar cell (the experimental cell). The metals deposited are copper and zinc. The ratios of *f*:*d* vary from 90:10 up to 95:5, and the ratios between the amounts deposited in the experimental and comparison cells vary from 75.6:100 to 88.8:100. The results show that the metallic deposits produced by such alternating currents are denser than those produced by continuous currents. But they are not sufficiently extensive to show how high the ratio of *f*:*d* can be chosen, nor do they indicate what is the most suitable frequency of alternation.—D. E. J.

PATENTS.

Sulphide Ores containing Zinc in Association with other Metal or Metals; Improvements in the Treatment of, for the Separation and Obtainment of Metals contained

therein. T. Parker, Tettenhall, Staffordshire. Eng. Pat. 24,861, Dec. 21, 1894.

Roasted ore is treated with dilute sulphuric acid, and the solution is caused to circulate through electrolytic cells, until by deposition of most of the zinc and re-formation of sulphuric acid, the acid strength of the solution is restored; it is then used for treating a fresh quantity of roasted ore, and so on. Fresh sulphuric acid is added occasionally to make good any loss. The negative electrode is zinc or other suitable substance, the positive lead; but when hydrochloric acid is used instead of sulphuric, a carbon or other chlorine-resisting positive is used, and the electrodes are separated by a diaphragm, whilst the residual solution is not used again. A suitable diaphragm is figured and described, having vertical wooden bars, connected at the ends by cross bars and packed between with porous material (glass wool).—D. A. L.

Electro-Deposition of Iron on Copper or other Metallic Surfaces, Improvements relating to the. A. Horns, Hanley, Stafford. Eng. Pat. 4660, March 5, 1895.

THESE improvements relate to the facing of copper plates with iron. The plates are dipped in a solution of potash at 80° F., scoured with a mixture of soda lime and powdered pumice stone, and washed in water. The "striking" bath is made up of 7 oz. of ammonio-sulphate of iron to 1 gall. of water, the anode being of Swedish or other "pure" iron. A potential difference of above 5 volts is employed on this bath. The plates are removed, again scoured, and treated in a bath of ferrous sulphate, 6 oz., ammonium chloride, 3 oz., to 1 gall. of water, worked at a temperature of 120° F., with a potential difference of 1 volt. Old plates to be re-coated are stripped in sulphuric acid solution, 1 of acid to 10 of water, kept at a temperature of 80° F. A dilute solution of potassium cyanide is used for cleaning copper plates from stains, so as to be ready to receive an iron deposit.—J. C. R.

Analysis, Electro-Chemical Method; which can be usefully applied. B. Neumann. Zeits. f. Elektrochem. 2, 231—235; 252—262; 269—272.

XII.—FATS, OILS, AND SOAP.

Cocoa-Butter, Iodine Number and Refractive Index of. A. Strohl. Zeits. anal. Chem. 1896, 35, 166.

SAMPLES prepared from all known trade varieties of Cacao gave iodine numbers varying from 32.8 to 41.7. The same variety may give different numbers according to the year, place of origin, or ripeness of the fruit. The refractive indices, determined at 40°, fell between 1.4565 and 1.4578. A low iodine number is generally accompanied by a low refractive index and *vice versa*.—A. C. W.

Cerotic and Melissic Acids existing Free in Beeswax, Properties of. T. Marie. Bull. Soc. Chim. 1896, 15, 510.

THE results of analyses of cerotic acid and its esters agree with the formulae $C_{25}H_{50}O_2$ or $C_{26}H_{52}O_2$ for the acid. Cerotic acid is easily soluble in methyl alcohol and in ether, melissic acid only slightly. Methyl cerotate crystallises in nearly microscopic needles melting at 62.5° C. (Nalzgier gives 60°). Methyl melissate has the same appearance and melts at 74.5° C. Pure cerotic acid in 1 per cent. boiling alcoholic solution gives no precipitate with magnesium acetate; the salt separates on cooling to 50°, but if the cerotic acid contain melissic acid, there is an immediate precipitate.

—A. C. W.

Fatty Acids, The Oxidation of. T. Marie. Bull. Soc. Chim. 1896, 15, 508.

COMMERCIAL stearic acid was oxidised by alkaline permanganate. From the mixture of acids produced, an acid was isolated by taking advantage of the great solubility of its barium salt. This acid, boiled at 181°—185°, and had the odour of normal valeric acid. The barium salt is stable

and does not smell of ordinary valeric acid; hence, contrary to general statement, normal and not iso-valeric acid is produced on the oxidation of stearic acid.—A. C. W.

XXIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A.)—PIGMENTS, PAINTS.

Antimony Vermilion, Formation of. J. H. Long. J. Amer. Chem. Soc. 18, [4], 342—347.

THE antimony vermilion prepared in the usual manner by boiling a solution of tartrate or chloride of antimony with sodium or calcium thiosulphate, is impure from the presence of oxychloride. By employing tartar emetic and sodium thiosulphate a pure vermilion was obtained, which analytical results indicated to be Sb_2S_3 .

Attempts made to produce the characteristic red pigment by methods (such as the action of sulphides or sulphur dioxide) other than those comprising the action of thiosulphates on neutral or acid antimony compounds, failed, although the product obtained may be antimony sulphide, the formation of the vermilion being apparently preceded by that of an intermediate yellow product, which suggests that Sb_2O_3 is at first formed from the tartar emetic and then acted on by the free thiosulphuric acid. This view was confirmed by the behaviour of pure antimony trioxide when exposed to the action of solutions of thiosulphate, no

vermilion being formed until the mixture is acidified with hydrogen chloride. That the reaction does not commence by the formation of antimony chloride is shown by the failure to precipitate anything but sulphur when the acid is shaken up with the oxide and the thiosulphate added to the filtrate, whereas if the acid and thiosulphate be first mixed and the oxide subsequently added, even after opalescence has set in, the vermilion begins to come down almost immediately.

In working with the pure trioxide, however, it is not found possible to convert the whole into vermilion, even after exposure for two months, and the amount converted diminishes as the percentage of thiosulphuric acid increases, which is probably due to the greater tendency of the stronger solutions to decompose, with evolution of sulphur dioxide, which in turn subsequently delays the action of the remaining thiosulphuric acid—a fact experimentally demonstrated by the author.

From oxychloride of antimony and thiosulphate the vermilion can be readily prepared, without the presence of any other acid than that resulting from the decomposition of the oxychloride in water.—C. S.

Zinc White, Cause of Yellow Colour of. F. Fuchs and F. Schiff. Oesterr. Zeits. Berg. u. Huttenw. 1896, 44, 29.

CERTAIN samples of zinc oxide, in spite of every endeavour to maintain the manufacturing conditions constant, have a yellow tint which detracts from their commercial value. This discoloration is commonly attributed to the presence of iron. Investigation made with a large quantity of the material proved the absence of iron, but led to the detection of 0.003 per cent. of cadmium sulphide. Seeing that zinc invariably contains cadmium, the fortuitous presence of sulphur would cause the presence of the strongly coloured sulphide. Similarly, small quantities of cadmium oxide or oxide of iron have no sensible influence on the colour. In order to restore the pure white of the zinc oxide it suffices to convert the cadmium sulphide into cadmium oxide by several hours' roasting in air, but a more radical remedy naturally consists in the choice of pure zinc for the production of the pigment.—B. B.

(B.)—RESINS, VARNISHES.

Preliminary Report on Two Burmese Turpentine. H. E. Armstrong. Imp. Inst. Scient. and Tech. Research Department Journal, May 1896, 182.

THE crude turpentine from *Pinus Khasya* was a grey, thick, pasty mass, containing a quantity of small pieces of wood. That from *Pinus Merkusii* was more fluid and cleaner in appearance.

About $\frac{1}{100}$ ths of its weight of oil was separated from the *Pinus Khasya* turpentine by distilling with steam, and nearly $\frac{1}{100}$ ths from the *Pinus Merkusii* turpentine. On a previous occasion nearly 17 per cent. of oil was obtained from a sample of the first-named turpentine.

The original turpentine and the distilled oil, in each case, have a very slight but agreeable odour, even less pronounced than that of French turpentine. The two oils are very similar in this respect.

The oil from *Pinus Khasya* appears to be identical with that which the author received from the Colonial and Indian

Exhibition, and examined several years ago, but which he was then led to believe came from the same tree.

The examination of oils of this description with a view to determine their precise composition is a matter of great difficulty. The oil from *Pinus Khasya* is strictly comparable with French oil of turpentine.

The oil from *Pinus Merkusi* is very similar to that from *Pinus Khasya*.

Like French oil of turpentine, both these oils distil within a very narrow range of temperature, near to 155° C., but the oil from *Pinus Khasya* appears to contain a somewhat larger proportion of a constituent of higher boiling point.

The two oils are very nearly alike in relative density viz.:—

	<i>P. Khasya</i>	<i>P. Merkusi</i>
at 20° C.	0.8627	0.8610

They both turn the ray of polarised light to the right, the so-called specific rotatory power being—

<i>P. Khasya</i>	<i>P. Merkusi</i>
+ 36'' 28	+ 31'' 45

The rotatory power of French turpentine is practically always about 36''. The *Pinus Khasya* oil now examined, agrees with that previously obtained from British Burma.

Practically, French oil of turpentine and that from *Pinus Khasya* exactly correspond in properties.

Both these Burmese oils are of the highest quality, and the author believes they would serve every purpose for which oil of turpentine (French or American) is used. They even compare favourably with the French oil, which is the highest quality in the market.

The resin left on distilling off the oil would also, the author believes, be available for all purposes for which ordinary resin is used.

There is no reason, he thinks, why India should not obtain whatever turpentine is required from native sources, if the industry can be developed, and the cost of carriage be not too great.

Varnish [Amber and Copal], Improvements in the Manufacture of. H. Flemming, Cologne. Eng. Pat. 8915, May 4, 1895.

In order to avoid the necessity for melting amber and copal before making them into varnishes, according to this patent the solvent properties of the chlorhydrins of glycerin, especially the di- and the tri-chlorhydrin, are made use of. One part of dry powdered gum kauri is moistened with an equal weight of the said solvent, and after a time two parts of alcohol are introduced, the mixture being warmed till solution is effected. 10 to 15 per cent. of linseed oil is finally added to complete the material. It forms a quick-drying varnish, which may be applied to wood without previous "filling"; and it will bear pumice stone, or polishing with linseed oil.—F. H. L.

Linoleum, Kamptulicon, and other Floor Coverings, Improvements in or relating to the Manufacture of. K. Klie, Lancaster. Eng. Pat. 18,937, Oct. 9, 1895.

PATENTS.

Gutta-Percha or its Compounds, Treating for the Manufacture of Golf Balls and other Goods, Improvements in. J. H. R. Paterson, Edinburgh. Eng. Pat. 10,715, May 30, 1895.

THE object of this patent is to refine gutta-percha in such a manner that it shall be white throughout, and therefore the better suited for the purposes indicated. The crude material is treated with petroleum spirit (sp. gr. 0.7) at 40°—55° C. Water, somewhat less in volume than the solvent, is added, and the whole agitated violently, and allowed to settle. The clear solution is drawn off, the aqueous residue washed with more spirit, and the insoluble portion thrown away. The whole of the gutta solution is then bleached with sulphurous or hypochlorous acid, well washed again in water, and finally the substance is precipitated by cooling the liquid below 18° C. During this cooling process pigments may be introduced if desired. The gutta paste is placed in a centrifugal machine, washed with fresh light petroleum to free it from resin, dried in a current of air, and finally kneaded under rolls or by other means.—F. H. L.

Waterproof Textile and other Fabrics, Ornamental and other Designs upon, Improvements in the Production of. L. Mistov-ski, Heywood, Lancashire. Eng. Pat. 21,511, Nov. 13, 1895.

GLASS, reduced to an impalpable powder and thoroughly sifted, is applied to the waterproofed fabric, either uniformly all over or in the form of a particular design. This produces a "soft, silky, and luminous effect." If further ornamentation, such as the application of colours, &c., be adopted, a second coat of glass may be employed to obtain a "shot" effect, before the final vulcanisation. Eng. Pat. 1297, 1895 (this Journal, 1895, 748) is referred to.

Tannin Estimation, Remarks on the Vienna Method of. J. Schneider. Časopis českého lékařnictva, 1896, 15, 4.

See under XXIII., page 385.

PATENTS.

Leather, Artificial, Manufacture of. O. Thiele and J. Stocker, Stargard, Pomerania, Germany. Eng. Pat. 8960, May 6, 1895.

THE mode of manufacture is as follows:—(1) 5 parts of bone glue are dissolved in linseed oil heated to 100° C., or in tannin solution, or glycerin and paraffin. (2) 5 parts of caoutchouc and 10 parts of colophony or other resin are dissolved in 100 parts of sulphide of carbon and 6 parts of spirits. The solution of these materials occupies from 12 to 24 hours. The two solutions are mixed, with continuous stirring, in a glazed closed vessel. (3) 50 parts of ivory nuts, cocoa or para nuts, are ground, boiled in glue solution, and then dried. (4) 50 parts of cotton fibre, or wool or other fibre, are finely divided by suitable machinery. The materials referred to under (3) and (4) are combined with those referred to under (1) and (2) by working them together for a sufficient length of time in a rag engine, and during this process 5 parts of carbonate of lime, and such colouring matters as may be required, are incorporated with the mass. In order to produce a good white colour, 5 parts of camphor must be dissolved in process (1) or (2), it being then possible to effect a thorough bleaching. A silky lustre is imparted to the material by adding to the product of operations (1) to (4) a little acetic acid and boiling for five minutes.

When the working of the mixture in the rag engine has been continued sufficiently long, the product is spread out and dried in the air for 1 or 2 hours. The dried mass is

rolled to the desired thickness and then passed through a mixture of concentrated nitric and sulphuric acids in order to remove the fibrous particles visible on the surface and to impart to the whole a homogeneous, horn-like appearance. Washing and drying follow, and the mass is introduced into a solution of camphor in ether; it is then again rolled, the rollers being heated to about 50° C. The proportions above given can be varied within certain limits. A recipe for the substitution of bone glue for caoutchouc is given.—A. G. B.

XVI.—SUGAR, STARCH, GUM, Etc.

Sugar Industry, Advance in, for the Last Quarter of 1895. Dingler's Polytech. J. 1896, 299, 118 and 166.

J. MÜLLER (Die deutsch. Zuckerind. 1895, 20, 1713) has found that the sugar prepared from beetroots infected with dry-rot has a grey colour. Inasmuch as the juice from such roots contains alkaline sulphides and salts of iron, a double sulphide of potassium and iron is formed, the sodium analogue of which is well known in the soda industry as an objectionable compound possessing considerable tinctorial properties. According to Lunge's investigations, this sulpho compound, even when present in some parts per million, produces a pale to dark green or brown coloration according to the concentration. Now a combination of the dark green with the natural yellow colour of the raw sugar will give rise to a grey-coloured product. If dilute acetic acid be poured over grey sugars, the sulpho salt is decomposed, and the yellow colour of the raw sugar reappears. The sulpho salt is soluble in the alkaline sugar liquor, and is partially precipitated, but never completely, during the saturation process, a portion remaining in solution even when the reaction of the liquor is neutral. The sulpho salt may perhaps be formed by the decomposition of albuminoids, or it may owe its origin to the presence of sulphuretted hydrogen in the carbon dioxide employed for saturation. The juice from normal beet always has an alkaline reaction, and sulphuretted hydrogen cannot be detected in it. Notwithstanding the fact that the juice is warmed to 80° C., the albuminoids can only partially separate, for they were found in the scum which forms over the boiling mash. If slaked or unslaked lime be added to raw juice raised to 80° C. according to the time and the quantity of lime employed, the filtrate gives a distinct brown coloration with basic lead acetate, which indicates the presence of alkaline sulphides. Conditions of working which hinder the precipitation of the albuminoids before the addition of lime, such as alkaline raw juice, inefficient preliminary heaters, the adoption of too low a temperature during diffusion, an undue addition of lime, or inappropriate defeccation with

caustic lime, tend to produce a grey coloration of the raw sugar. The sulpho salt may be decomposed by passing a compressed current of air through the warm liquor at the first saturation. If carbon dioxide gas of about 20—29 per cent. be made use of, which contains about 6—10 per cent. of oxygen, it is probable that the decomposition of the sulpho salt is attained.

Maxwell (Sugar Cane, 1895, 27, 575) has investigated the efficacy of certain chemical substances employed in defeccating raw juice, namely, sulphurous acid, acid phosphate of lime, and lime. When gaseous sulphurous acid is passed into the juice, the density is raised to 0.3° Bx., with moderate decolorisation and coagulation. The inversion is slight in the cold, very appreciable at 60°, and considerable in the case of hot thick liquor through which the gas has been passed until good decolorisation is attained. Acidity due to calcium acid phosphate has about the same inverting power as that due to sulphurous acid, and accordingly appears to invert sugar more readily than phosphoric acid. Sulphurous is more efficacious as an antiseptic than other acids. Both agents precipitate the albuminoids present in the juice, but sulphurous acid only does so when a considerable quantity has been absorbed. Gums or pectins are not precipitated by either of these agents, although lime at a high temperature effects their precipitation, as also that of the greater portion of the albuminoids. In consequence of the inversion caused by acidic defeccating agents, the juice should only be treated with them in the cold, and must be neutralised before heating with lime. Good working results are attained if the juice, after being rendered alkaline with lime, is neutralised with acid phosphate and heated. It is, however, advisable to make use of sufficient phosphate to produce an acid reaction, otherwise much lime will remain in the juice, in combination with organic acids, and the acidity produced by the organic acids set free by the small excess of phosphate causes but slight inversion.

The bleaching effect of sulphurous acid takes place only in acid solution; after the neutralisation the juices which have been treated with phosphates are usually better in colour because it causes the precipitation of pigments. Sulphurous acid has, however, a strong bleaching effect upon caramel-like products.—J. L. B.

Sugars, Molecular Modifications of, The Cause of Multi-rotation. C. Tanret. Bull. Soc. Chim. 1896, 15, 349—351.

It is shown that certain sugars can exist in two or more isomeric forms, each possessing a rotatory power peculiar to itself, and that bi-rotation and other changes in the rotatory power observed under varying experimental conditions (alterations in the concentration of solutions, influence of heat, alcohol) are due to the preponderance—in any particular case—of one of these modifications.

When a sugar is dissolved in water, the β - (or ordinary stable) modification is formed. The transformation is complete, however, only in dilute solutions. Beyond certain limits of concentration, the conversion of the solid (α -) sugar into the β -variety is only partially effected, and in consequence the rotatory power is increased. This is particularly the case with dextrose and galactose. The rotation of a concentrated solution, falls, not immediately, but gradually to the normal value, when diluted with water. The specific rotation of a sugar in alcoholic solution may be greater or less than in aqueous solution. In the former case this is due either to its incomplete transformation into the β -modification, or to the formation of a third variety possessing increased optical activity. Similarly, a diminution in the rotatory power is owing to the production of a third (γ -) species of the sugar. In the case of galactose the γ -modification has been isolated in the crystalline state. In general, the influence of heat on sugar solutions resembles that of alcohol; both diminish the specific rotation of lactose, galactose, and arabinose, and increase that of xylose. On the other hand, the rotation of dextrose, although diminished by alcohol, is only sensibly influenced in very strong solutions at an elevated temperature, by heat.

—H. T. P.

Beetroot in Germany. Chamber of Commerce Journal, April 1896, 58.

From the results of the campaign of 1895-96, the difference in the production of beetroot in Germany as compared with that of France appears to be a very drastic one. The *Freisinnige Zeitung* reports on the subject of statistics for January as follows:—

	Germany.	France.
Factories in operation	397	255
Area planted with beetroot..... Hk.	374,174	200,000
Crop of beetroot harvested..... T.	11,672,000	5,411,000
Sugar produced.....	1,610,000	670,000
Production of sugar per head... Qs.	13'03	33'18
Production of beetroot per head ..	311'94	270'42
Sugar obtained from beetroot .. "	13'25	12'00
Beetroot worked up per factory .. Qs.	294'00	152'420
Receipts from the production of .. M.	0'900	0'770
sugar per head (28 M. per 100 kilos.).		
Quantity of beetroot required to .. Qs.	7'25	8'08
produce 1 q. of sugar.		

According to these figures the production of beetroot and sugar per head, also the yield of the beetroot, is therefore considerably larger in Germany than in France, and our contemporary remarks that they speak very powerfully against an increase in the premium.

PATENTS.

Starch from Raw or Crude Starch, Process for obtaining Pure. W. von Siemens, Berlin, and O. N. Witt, Berlin. Eng. Pat. 24,455, Dec. 20, 1895.

By "raw or crude starch" the inventors mean the starchy product obtained from cereals, &c. by levigation in the usual manner. The object of this invention is to prepare from this a pure starch which will be colourless, and have the cellulose membrane of the starch grain so acted upon as to readily yield to any chemical treatment; a starch thus prepared is readily converted into sugar by mineral acids without a vestige of bad odour and yields a perfectly smooth paste when treated with boiling water or potash, &c. This pure starch is prepared as follows:—The crude starch is stirred up with water, and a saturated solution of potassium permanganate is added until the pink colour of the latter persists in the liquid. The manganese peroxide formed by the decomposition of the permanganate is deposited in a state of extreme division on the starch, which thereby assumes a brown colour. The starch is then well washed and treated with a dilute solution of hydrochloric acid, varying, according to the nature of the starch, from 0.5 per cent. As soon as a sample of the starch when treated with alkali gives a perfectly clear solution, the starch is filtered off and freed from excess of manganese peroxide by sulphurous acid or dilute bisulphite, washed, and dried.

—A. L. S.

Sugar-refining, Improvements in. M. Zahn, Artern, Thuringia, Germany. Eng. Pat. 3565, March 21, 1896.

In place of using ordinary steam for washing sugar in the centrifugals, the inventor proposes to use superheated steam; by so doing he states that much loss of sugar is avoided. Also he introduces into the last portion of the steam the required amount of "blue" mixed with a small quantity of water or syrup, and thus the bleaching of the sugar is conveniently effected.—A. L. S.

XVII.—BREWING, WINES, SPIRITS, Etc.

Fermentations caused by Friedländer's Pneumococcus.

L. Grünbert. Bull. Soc. Chim. 1896, 87-96.

THE results obtained in the fermentation referred to are summed up as follows:—1. The products of the fermentation are, ethyl alcohol, acetic acid, levo-rotatory lactic acid, and succinic acid. 2. Whilst, however, glucose, galactose, arabinose, mannite, and glycerin give levo-rotatory lactic acid and no succinic acid, saccharose, lactose, and maltose give both, whilst dulcitol, dextrin, and potatoes produce only

succinic acid without a trace of lactic acid. 3. The acetic acid produced, is always obtained pure and free from both formic and propionic acids. 4. Ethyl alcohol is formed in smaller quantities than the other products, in some cases being absent, as in the fermentations of potatoes and arabinose, and only present in traces in the fermentations of glucose, saccharose, or maltose. In dextrin fermentations it is mixed with a small quantity of higher alcohols. 5. Most striking is the behaviour of the two isomerides mannite and dulcitol, the former giving levo-rotatory lactic acid, whilst the latter yields only succinic acid, furnishing a rare example of a ferment giving different products according to the nature of the sugar decomposed.—T. A. L.

Schizosaccharomyces Pombe, The Dextrin-fermenting Yeast, and its Practical Employment. F. Rothenbach. Zeits. für Spiritusind. 1896, 19, 58, 59, 71, 87, 88, 104, 105, 111, 112, 119, 120.

This yeast was first described by Saare, who obtained it from an African beer (Zeits. für Branerei, 1890). See also this Journal, 1896, 127.

It is considered to ferment dextrin, as it will attenuate malt worts lower than Frobberg yeast, the latter being considered able to ferment all the sugars present. However, to place the matter beyond doubt, a solution of dextrin was prepared which gave no coloration with iodine and no osazone with phenylhydrazine, a little asparagin and mineral nutritive matter were added, and the solution seeded with this yeast. About one-half of the dextrin was fermented.

At temperatures of 55°—65° F. Pombe yeast ferments slowly and acts like a low-fermentation yeast; at temperatures of 85°—95° F., fermentation proceeds very rapidly and as with high-fermentation yeasts. Pombe yeast produces a much larger amount of acidity than other yeasts, nearly or quite 10 times as much; it has a destructive action on bacteria; when sown in a malt wort which had been strongly infected with various bacteria, it fermented as usual, and during the fermentation the bacteria were found to be destroyed; this latter property has probably some connection with its acid-producing power.

Comparative experiments were made on the attenuative power of Pombe yeast and a distillery yeast of high attenuative power; a wort was prepared such as would occur in a distillery, containing free diastase; the former yeast was always found to attenuate the wort the most; and when mixtures of the two yeasts were employed the attenuation was always considerably lower, a result which may perhaps be caused by the enzyme of Pombe yeast hydrolysing the dextrin to sugar, which is then fermented by the other yeast.

In a wort prepared from potatoes, Pombe yeast does not increase satisfactorily; this difficulty was, however, overcome by the addition of a small quantity of ammonium phosphate. Some fermentations were made on the large scale in distilleries, pitching with Pombe yeast instead of that usually employed; they were not at all satisfactory, the difficulties being chiefly caused by too slow reproduction and fermentation.—A. L. S.

Malt and Beer Worts, Nitrogenous Constituents of.

E. Erich. Der Bierbräuer, 1895, 10, 146.

THE conclusions are:—

1. The analytical separation of albuminoids, peptones, and amides cannot as yet be satisfactorily effected. By Stutzer's method (copper hydrate and phosphotungstic acid) more peptones but less amides and albuminoids are found than by the lead acetate tannin process. In the latter, the filtrate from the albumin precipitate should be completely freed from lead before the separation of the peptones is attempted.

2. During the germination of barley, the albuminoids are peptonised to an extent proportionate to the degree of growth—at least within the limits obtaining in practical malting. At the same time, those constituents that produce turbidity (glutens) correspondingly disappear.

3. A further peptonisation of the albuminoids takes place when malt is mashed, the temperature most favourable to the action being about 50° C. A slight tendency to gluten

turbidity may be overcome by prolonged mashing at the above temperature.

4. In respect to nutritive power as yeast-food, peptones and amides are about on a level, and both greatly excel the albuminoids.—H. T. P.

Lupulin, Chemical Constituents of. H. Seyffert and R. v. Antropoff. Zeits. f. d. ges. Brauwesen, 1896, 19, 1—5.

The results arrived at are summarised as follows:—
1. Bungener's acid (Hopfenbittersäure) is identical with the β -acid obtained from the petroleum ether or ethereal extract, after precipitation of the α -body with lead acetate.
2. The α - and β -acids, on treatment of their ethereal solutions with potash, suffer no decomposition beyond the formation of a slight amount of resin.
3. Lerner's acid (Bittersäure) cannot be identical with the α -acid.
4. Besides the two known α - and β -acids, no third crystalline substance of similar nature could be detected. The yellow crystalline substance found in the γ -resin appears to possess the character of a weak acid, but to belong to a quite different class of compounds.
5. The hop resins are mixtures of substances in different stages of decomposition; Hayduck's modifications appear to be present in the decomposition products.
6. The quantitative determination of the α - and β -substances can be best effected by extraction of the hops with ether, evaporating the extract, and exhausting the residue with petroleum ether.—A. K. M.

Wines, Sweet; Investigation and Valuation of. M. Barth. Forschungsber. Lebensmittel, Hyg., forens. Chem., Pharmakogn. 1896, 3, 20.

TOKAY wines partake of the character of concentrated wines made from somewhat over-ripe grapes without addition of sugar or alcohol. Szamorodni wine contains in 100 c.c. at least 3 grms. of sugar-free extract, 0.2 gm. ash, and 0.04 gm. phosphoric acid. The glycerin content is proportionally high, and never falls below the observed limit for the better German wines. The sugar consists chiefly (70 per cent. or more) of levulose. In sweet Tokay of the first quality the sugar-free extract amounts, even in the poorer specimens, to 3.5 grms. per 100 c.c., and with a sugar content of 8 per cent. and upwards it is at least 4 grms. per 100 c.c. The ash in the same brand is not lower than 0.25 gm. per 100 c.c., nor is the phosphoric acid lower than 0.06 gm. per 100 c.c.; the proportion of glycerin to alcohol is very high. The common Hungarian sweet wines also have a sugar-free extract of 3 grms., an ash of 0.24 gm., and a phosphoric acid content of 0.04 gm. per 100 c.c.; the glycerin is somewhat lower than it is in German wines, and levulose is the predominant sugar. The so-called Greek dry wines are not concentrated wines; they contain 2.4 grms. of sugar-free extract, 0.2 gm. of ash, and 0.017 gm. of phosphoric acid per 100 c.c.; if they contain added alcohol, this is not more than 2 per cent.; levulose forms the larger portion of the little still unfermented sugar. Greek sweet wines contain at least 3 grms. of sugar-free extract, 0.24 gm. of ash, and 0.03 gm. of phosphoric acid per 100 c.c. The glycerin content of these wines is lower than that of Tokay wines, since added alcohol is present, although at least 6 grms. of alcohol per 100 c.c. are derived from fermentation of the must; levulose is the preponderating sugar and its proportion to the dextrose varies from 55:45 to 66:34. The sulphuric acid should not exceed 0.092 gm., nor the chlorine 0.03 gm. per 100 c.c.

The methods adopted for the examination of the above wines were those commonly in use.—A. G. B.

Wine, Occurrence of Copper in. H. Karsten. Zeits. österr. Apoth. Ver. 1896, 34, 84.

In Switzerland, attacks resembling those of dysentery, following the consumption of a certain wine, were traced by the author to the use of copper sulphate as a means of protecting the grape vines from the ravages of disease fungi. Copper sulphate solution is employed in the form

of a spray, and appears to be in some way retained by the unripe grapes. A polished knife blade dipped into the wine in question for 12 hours became covered with a distinct film of metallic copper.—H. T. P.

Alcohol Vinegar, Insufficiency of the Methods employed for the Detection of. H. Quantin. Monit. Scient. 1896, March, 10, 171—176.

SINCE it is impossible to trace "wine vinegars" chemically to their natural source, it is necessary to make a further study of the properties of such vinegars for the purpose of identification. In the meantime it is proposed to make compulsory the introduction into the alcohol used in manufactures of some substance readily detected, and at the same time unobjectionable from a hygienic point of view. Phenolphthalein would be very suitable, and in quantities of 5—6 mgrm. per litre is quite harmless. By this addition the object in view would be precisely attained.—N. H. J. M.

Yeast, Improvements in and relating to the Production of. H. H. Lake, London. From J. Effront, Brussels, Belgium. Eng. Pat. 4598, March 4, 1895.

YEAST is cultivated in a wort prepared from maize, rice, or other cereals, to which has been added a small amount of hydrofluoric acid, salicylic acid, or other antiseptic. The crop of yeast is then sown in a similar wort containing a greater amount of antiseptic, and the crop obtained in one containing a still greater amount, and so on until the amount of antiseptic is as great as possible. The yeast is then separated by filtering the whole of the fermented wort through a filter press, and the pressed yeast dried by exposure to the air or in a suitable vacuum apparatus, but not at a higher temperature than 40° or 50° C. Yeast thus prepared is said to retain its vitality for a length of time.

The claim is for a process of preparing a special yeast called "dregs yeast," the characteristic feature being the recovery of the yeast from a fermented wort, by retaining it with the said dregs by filtration and desiccation. The yeast obtained is, it is said, of particular physiological character, and of an absolute unchangeability.—A. L. S.

Grain, Pneumatic Malting of; Improvements in or relating to the. A. Kinder, London, and H. Baird, Glasgow. Eng. Pat. 6661, April 1, 1895.

IN the working of a pneumatic malting drum, difficulty has been found in passing the air uniformly through the whole mass of the grain, as the thickness of grain between the inlet and outlet channel is much less in that portion of the drum which happens to be uppermost at any one time. In order to obviate this the inventors propose to shut off the air current from that portion of the drum. This is effected by two radial vanes pivotally mounted within the central air conduit; these vanes extend from end to end of the conduit. Each end of the space occupied by the vanes is suitably blocked, so that the space between them forms a closed chamber from which the air currents are excluded.

During the latter stages of malting, instead of passing fresh air through the grain, the inventors circulate the air over and over again; by so doing they claim that the withering is more efficient. The air is suitably attempted between each passage.—A. L. S.

Brewers' Refuse, Grains, and the Whe, Improvements in or relating to Apparatus for Drying. E. Makin, Manchester. Eng. Pat. 9835, May 18, 1895.

THIS relates to improvements of Eng. Pat. 18,833 of 1891 (this Journal, 1892, 932). The substances to be dried are introduced into the hot-air current as it enters the rotating drying drum. The dried material is carried forward by the air current and passes out with it. The interior of the drum is fitted with baffle plates in order to prevent a too rapid passage of the materials through it.—A. L. S.

Liquids, Fermented and Distilled, Improvements in Processes of Manufacturing. A. Myers, Philadelphia, U.S.A. Eng. Pat. 2587, Feb. 1, 1896.

In the preparation of a wort for distillers it is customary, when using raw grain, to employ a small quantity of malt, in order to supply the diastase necessary to convert the starch into sugar. The inventor states that the hull or bran of the grain, which is separated in the milling process, contains diastase, and may be substituted for the malt commonly used.

The bran is soaked in five to six times its weight of water at a temperature of 75° F. for from 18—36 hours. The mixture is added to the well-boiled mash when it has cooled to 155° F. in the proportion of 6—12 lb. of bran to each bushel of malt. The process is then carried on as usual.—A. L. S.

Matches in Belgium, Manufacture of. J. Soc Arts, 44, 1896, 526.

A RECENT number of the Bulletin of the Labour Bureau of France states that the following new regulations are in force in Belgium relative to the manufacture of matches. It is not to be considered sufficient in the future that the dipping plates of white phosphorus matches should be covered with hoods connected with a strong draught chimney; a suction tube connected with mechanical ventilation must be established on the level of the dipping plates and vessels which contain the paste. Respecting the composition of the pastes, they must not contain more than 80 per cent. of white phosphorus without reckoning water; the least infringement of this regulation will not be tolerated, as it is satisfactorily proved that an excellent match paste can be manufactured of this consistency. The dryers, except the tunnels in which workmen must remain, must in future be aired by mechanical ventilators. Permanent committees exist which are to fix the amount of air. The working tables upon which the white phosphorus matches are filled must likewise be ventilated so that the phosphorus vapours may be immediately drawn off to the lower part of the workshop and expelled. The ventilation must be such that, combined with the other causes of removal of the air in the workshops, the expulsion of the air per hour and per workman in each room where white phosphorus matches are handled, shall be at least 2,119 cb. ft. The removal of the air in the rooms where Swedish matches are handled must be 1,060 cb. ft. per hour and per workman, and further, each workman must always dispose of at least 353 cb. ft. of air. There must be in each factory a room where vessels containing water and soap for the use of the workmen shall be placed. The strictest control will be exercised in this respect. Workmen will be subject to a preliminary medical examination and afterwards to a monthly visit, the results of which are to be duly inscribed in a record book. They shall not be allowed to work from the time when they may have been attacked by phosphorus necrosis, or from the period when they appear to be threatened with an attack of this disease.

Paraffin and Mineral Oil Manufacture, The Gases and Effluents from. Chem. Zeit. 29, 1896, 2251—2253.

IN granting concessions to new enterprises, the authorities take into consideration the health of all persons dwelling within the immediate vicinity of such undertakings, and they further protect the agricultural interests in regard to possible injury to vegetation through the escape of gases, and the contamination of the soil by chemical effluents or deposits of flue dust from chimneys.

In considering from a hygienic point of view the methods by which brown coal (lignite) is decomposed, the question relating to the injurious effect of the flue dust on vegetation forms an important factor. In constructing works in which such effect is to be avoided, great stress must be laid on the erection of high chimneys provided with suitable pits for the removal of the flue dust. Maercker, who has investigated this point on behalf of a number of agriculturists, refers

to the general destruction to plant life brought about by the emission of fine dust, and although his remarks are well founded as regards delicate plants, it must be admitted that in the neighbourhood of works in which the destructive distillation of lignite is carried on, and from the chimneys of which fine dust is thrown out in large quantities, corn, potatoes, beetroot, clover, maize, and the like thrive in a remarkable manner. In fact, the luxurious growth of some plants, such as clover, is attributed to the fertilising effect of certain salts contained in the fine dust.

Brown coal is decomposed in vertical cylinders, the resulting gases being in part condensed to lignite tar, whilst the combustible gases are used as fuel for heating the cylinders. The percentage composition of the gases varies considerably with the temperature employed and the mode of firing. By maintaining a temperature of 150° to 160° in the cylinders, the highest yield of tar is obtained and the smallest proportion of non-combustible gas. According to Grotowsky the decomposition of brown coal commences at 112° , carbonic anhydride being liberated, with the formation of a small proportion of hydrocarbons. With a rise of temperature the quantity of the former is rapidly decreased, being to some extent replaced by carbonic oxide, whilst the amount of hydrocarbons is increased. At a red heat the elementary constituents of the coal are resolved into the so-called permanent gaseous hydrocarbons, especially illuminating gases. In addition to gaseous impurities the atmosphere of lignite-carbonising works is frequently contaminated with particles of coke dust, the inhalation of which gives rise to pulmonary complications and injury to the mucous membranes. The effluents, on the other hand, if free from tar and particles of coke, exercise a beneficial influence on vegetation.

The conclusions drawn indicate the fact that the gases derived from the destructive distillation of brown coal are detrimental to animal and vegetable life, unless they are diluted with a sufficient quantity of pure air, in which case it is estimated that at the most only 25 to 30 metres of the adjacent land would be exposed to the influence of the escaping gases. Beyond this distance it would be impossible to discern any prejudicial result.—D. B.

PATENTS.

Town Refuse, Improvements in Apparatus for Burning.

E. E. Glaskin, Harrow-on-the-Hill, Middlesex. Eng. Pat. 6175, March 25, 1895.

THE described apparatus consists of a crucible or combustion chamber supported within, and above the floor of, an annular brick setting, dome-shaped at the top, in such a manner that the products of combustion pass downwards, between the sides and bottom of the crucible and the setting, thus keeping the crucible hot. The crucible is supplied with a hot-air blast through tuyères, and has a loose cone-shaped bottom capable of vertical movement. A fire having been lighted and the crucible made thoroughly hot, the refuse is continuously fed in through a vertical shoot, mixed with fresh fuel if necessary. Part of the mineral matter fuses and escapes round the bottom of the crucible into the chamber below, the dust carried away by the blast settles in the same chamber, and the hot gases are led away through the flue of a boiler or are utilised in any other way.—L. A.

Water Purifying or Softening Apparatus, Improvements in. S. H. and P. E. Hodgkin, London. Eng. Pat. 7545, April 13, 1895.

THE improvements consist in arrangements (1) for intimately mixing the hard water and the reagent solution, and (2) for drawing off the reagent from a store tank under a constant head.—L. A.

Textile Materials and Fabrics, Improvements in the Treatment of. S. Simon and R. Dux, Manchester. Eng. Pat. 8858, May 4, 1895.

TEXTILE yarns and fabrics of any kind are impregnated with antifetorile substances, such as quinine and its salts, acetanilide, atipyrine, &c., the patentees being of opinion that the wearer of fabrics so impregnated will benefit by the action of these substances.—H. S.

Softening Water, Improvements in Apparatus for. C. E. Gittins, London. Eng. Pat. 9829, May 18, 1895.

THE patentee constructs the vessels containing the water to be softened and the reagents to be employed, of the same depth, whilst the respective areas are such as to correspond with the relative proportions in which it is desired to mix the water and reagents. Adjustable siphons are also employed for regulating the supply of the solutions or liquids, which are delivered into a lower cistern.—O. H.

Sewage and other Foul Waters, Improvements in, and in the Production of Compositions adapted to be used in the Treatment of. C. A. Burghardt, Manchester. Eng. Pat. 10,891, June 1, 1895.

A COMPOSITION or cake containing ferric and aluminium sulphates is made by taking an iron ore or any other substance consisting largely of hydratized ferric oxide, also lauxite or any other suitable material containing alumina, boiling the finely-ground substances with sulphuric acid until the iron and aluminium are converted into sulphates, and then evaporating the liquid until on cooling it will set into a cake. Or the ferric sulphate alone may be dissolved in water, a solution of aluminium sulphate added, and the mixed solution evaporated until it will set in a cake. The relative proportions of ferric oxide and alumina in the cake are controlled by analysis of the raw materials, and are varied according to requirements. (See also this Journal, 1894, 832.)—L. A.

(C).—DISINFECTANTS.

Argentine Republic: Sheep Scab and Sheep Dips.

N. S. Consular Reports, April 1895, 519.

See under Trade Report, page 588.

PATENTS.

Disinfecting Apparatus, Improvements in. W. Defries, London. Communicated by G. Herscher and Co., Paris. Eng. Pat. 8223, April 25, 1895.

THE improvements consist (1) in controlling the pressure in a steam disinfecter by causing the steam to blow through a seal of water, disinfectant solution, or other fluid, the depth of which regulates the temperature in the disinfecter; (2) in a disinfection stove in which the air for drying is heated by passage through tubes which pass through the steam space of the boiler; and (3) in an apparatus embodying the above improvements.—L. A.

Insecticides, Improvements in. I. S. and J. T. McDougall, London. Eng. Pat. 9535, May 14, 1895.

TO obviate the necessity of water for diluting a liquid insecticide in order to apply it as a wash, the liquid is incorporated with a suitable absorbent, and, by gently drying the mixture, a powder is produced which can be dusted over the plants. Examples of such mixtures are: (A.) Extract of tobacco, 10 lb.; precipitated sulphate of lime, 90 lb. (B.) Extract of tobacco, 5 lb.; extract of hellebore, 3 lb.; lac sulphur, 10 lb.; dry soap, 2 lb.; kieselguhr, 80 lb. (C.) Arseniate of potash or soda (solution), 2 lb.; extract of quassia, 8 lb.; vegetable fibre (finely powdered), 90 lb.—L. A.

XIX.—PAPER, PASTEBOARD, Etc.

Sulphite Wood Pulp Process, Sulphur, Consumption of, in the. H. Brünger. Papier Zeit. 1896, 21, [9], 260.

THE table given by the author shows the consumption of sulphur during the months of 1895, at the sulphite pulp mills of J. Halbmayer and Co., Josefsbütte, Bohemia, the absolute dry fibre being taken at 88 per cent. of the pulp.

In round numbers, it was found that 10 kilos. of sulphur were required for 100 kilos. of air-dried pulp (88 per cent.). The sulphur is taken as 100 per cent., and the system adopted consists in absorbing the sulphur dioxide by milk of lime.—S. P. E.

Sulphite Wood Pulp Process; Sulphur, Consumption of, in the. A. Frank. *Papier Zeit.* 1896, **21**, [12], 354-355.

In the preceding abstract, H. Brüngger publishes the monthly consumption of sulphur per 100 kilos. of pulp (88 per cent.) for the year 1895. Although these figures are valuable, and the results of actual practice, the circumstances and conditions of working at this mill must be taken into consideration before any comparison or conclusions can be deduced from them. It is a well-known fact that less sulphite liquor is required by those processes in which indirect steam is employed, as to the Mitscherlich system and Salomon-Brüngger system, as adopted at Josefshütte, than in the so-called Ritter-Kellner process, where steam passes into the liquor direct.

In the latter process a large quantity of steam is condensed, thereby diluting the liquor considerably and necessitating the occasional blowing off to waste of a quantity of unused liquor to give space for the introduction of fresh steam for heating the contents. It is also well known that a weaker liquor may be used for digesting the wood, if it be not required to remove the whole of the incrusting matter from the fibres. Such partially reduced pulp is most suitable for some purposes in which a strong fibre is necessary, but it requires more bleaching powder to whiten it than perfectly reduced fibre does.

The results given by Brüngger do not tell the amount formed of SO_2 and SO_3 respectively. In the author's own plant, in connection with a method for testing the product is provided (see Hofmann's Handbook, p. 1518), he can guarantee 95 per cent. of the sulphur in the form of SO_2 , and in well-conducted mills 98 per cent. is obtained. Without the knowledge of the quantity of SO_2 formed, the results are of little value. Brüngger's report of the consumption of sulphur for 1894 (see *Papier Zeit.* 1895, **2**, 33) shows that in July of that year, when the air was very moist, and the formation of SO_3 likely to be at its maximum, the consumption per 100 kilos. of pulp was only 8.75 kilos., whilst the highest consumption of sulphur was in February (11.3 kilos.). In the year 1895, the highest consumption was in the three summer months (June, July, and August), as might be expected. The author says that by carefully working and recovering the gases, it is easy to produce 100 kilos. of sulphite pulp per 10-11 kilos. of sulphur, even in processes where direct steam is employed.—S. P. E.

Wood Pulp, Moist; Storing of. F. Wolesky. *Papier Zeit.* 1896, **21**, [18], 563.

THE deterioration of moist wood pulp when stored, is largely due to the impurity of the water employed in grinding the wood.

Manufacturers employing clear, pure well or spring water for grinding, are able to produce a wood pulp capable of being stored for a considerable time without deterioration. If the water employed be taken from streams or ponds, which frequently contain a large number of micro-organisms and other decomposable matter, the pulp is very liable to become mildewed, or spotted with fungoid growths. Water containing any effluents from, or located in the vicinity of, breweries, sugar refineries, distilleries, or even sulphite pulp mills, is also liable to contain germs capable of developing an appearance of mildew in pulp. Impure waters such as the above should certainly be treated by some cheap purifying or sterilising agent. The durability of wood pulp may be increased by saturating it with various salt solutions in the process of manufacture, such as common salt, Epsom salt, or sulphate of alumina, which have no injurious effect upon the machinery, nor deteriorate the pulp for paper-making purposes.

These salts may be employed in solutions of $\frac{1}{20}$ th per cent., or more or less in proportion to the impurity of the water. A $\frac{1}{40}$ th per cent. solution of bisulphite of soda may with advantage be employed to improve the colour of the pulp. The store rooms should be large and airy, with a cement floor having a good fall, and plenty of water for cleansing purposes.—S. P. E.

Papers, Sulphite; Gunning of. *Papier Zeit.* 1896, **21**, [27], 861.

Users of sulphite papers complain that the hard and glossy nature of these papers is such that ordinary gum will not readily adhere to the surface. In reply to a correspondent who asks for a suitable gum, or a remedy, the above journal states that envelopes and wrapping papers composed of sulphite fibres owe their value to their beautiful glossy surface. When used for envelopes it is sometimes difficult to get the gum to adhere. The glossy surface refuses to take the gum solution. If resin size has been employed, the free resin fills the pores of the paper surface, and it naturally resists an aqueous solution of gum. This may be overcome by brushing the surface with a weak alkaline solution of soda. A solution of soda, however, destroys the size and also many colouring matters, and may therefore be unsuitable. The difficulty may in some cases be overcome by adding a little spirit to the gum. It is stated that gum arabic may be successfully employed.

—S. P. E.

Strawboards, Turning Yellow of the White Paper Coating. *Papier Zeit.* 1896, **21**, [26], 829.

IN reply to a question relating to the removal of lime from boiled straw pulp by washing, and to the cause of the white paper turning yellow when pasted on the strawboards, a correspondent in the above journal says that at his mill, about 150,000 kilos. of strawboards are coated with paper weekly. The operation is carried out on the machine, and the straw pulp is not washed, nor is this operation necessary if the pulp be properly boiled. The paper covering the boards does not turn yellow. In pasting them by hand it frequently happens that too much of the dilute paste is employed, the water of which saturates the surface of the board, and then penetrates through the paper, which upon drying develops a yellow coloration.—S. P. E.

Filter-Paper, Testing of. *Papier Zeit.* 1896, **21**, [7], 195.

A GOOD filtering paper suitable for chemical laboratory work should stand the following tests:—1. Distilled water after passing through the paper should not leave a residue upon evaporation. 2. Ammonium sulphide should not turn the paper brown. 3. A 10 per cent. solution of hydrochloric acid should not be coloured yellow after passing through the paper. 4. After passing dilute acids through the paper, and then saturating them with alkali, no milkiness should appear. 5. After passing dilute alkalis through the paper and then neutralising them with acids, no milkiness should result.

No. 1 test proves the absence of soluble salts, 2 and 3 of iron, 4 of salts of barium, calcium, and strontium, and 5 of greasy matters.—S. P. E.

Parchment Paper turning Yellow. *Papier Zeit.* 1896, **21**, [2], 34.

THE cause of parchment paper turning yellow is frequently due to the presence of lead, which becomes acted upon by sulphuretted hydrogen in the air. The presence of lead in the parchment is due to the fact that the sulphuric acid employed in its production, had been stored in lead vessels. A large number of samples of parchment paper showed the presence of iron, probably derived from the drying cylinders through the action of the trace of acid left in the paper.—S. P. E.

Animal Sizing [Paper]. Clayton Bandle. *The Paper Maker*, Vol. **11**, No. 3, 153-157.

IN order to determine the comparative values of different classes of gelatin upon waterleaf paper, solutions were made of such strength that a gallon of each solution contained an equal value of gelatin. Waterleaf paper was soaked in each solution, and after the removal of the excess of solution the sheets were dried, and the amount of gelatin retained by the paper was calculated from the increase in weight. The results are summarised in a table. The author concludes therefrom: (1) That there is great regularity in the amount retained in each series.

(2) That the amount retained by each series is proportionate to the concentration of the solution. (3.) That the finer grade gelatins are cheaper in the end.

In making a comparison of the "gelatinising power" of different gelatins with their sizing effect, the author comes to the conclusion that the sizing effect of a gelatin is in proportion to its "gelatinising power."

In another table are given the results of a trial in which sheets of paper are sized with diminishing quantities of gelatin, in order to determine the minimum amount thereof necessary to produce a "hard-sized" paper. The paper was found to be hard-sized when it contained 4.5 per cent. of gelatin, but below this amount it could not be said to be hard-sized. The relative merits of "single-sheet sizing" and "web sizing" are discussed. By the former process a hard-sized paper can be obtained with much less gelatin than is necessary in the latter. The imperfection of the latter process is largely due to the rapidity of the drying and the high temperature of the air. The success in sizing, in the author's opinion, largely depends upon allowing the sizing solution with which the paper is permeated, to solidify to a jelly first of all, and then to dry at a temperature below the melting point of the jelly. When these precautions are not observed the films which seal the interstices become dispersed, and the paper often becomes soft-sized.

An easy method for calculating the amount of gelatin absorbed by the paper whilst passing through the sizing trough, is given for the use of manufacturers.

About 40 determinations of the amount of gelatin in the web of paper as it passed over the dryers, were made. The conditions were so complex that it was difficult to arrive at any definite conclusions. No connection could be traced between the thickness of the paper and the amount of gelatin absorbed. The amount retained was found to vary very much with the composition of the paper. It was found on an average that hard-sized papers absorbed their own weight of the gelatin solution. It is fair to assume that for each ton of the above paper 220 gallons of water have to be evaporated during the drying of the sized paper, and that 235 gallons of the sizing solution have to be supplied to the sizing trough.—C. B.

Canadian Wood-Pulp Industry. Board of Trade Journal, May 1896, 601.

THE *Canadian Gazette* states that the Dominion Government has now under consideration a proposal which has often been urged upon Canada for an export duty of 2 dols. per cord upon pulp wood, so as to discourage the export of the raw material from Canada, and encourage its manufacture into pulp in Canadian mills. At present the United States tax on imported pulp is 10 per cent., while pulp wood is free. A Canadian export duty would, it is claimed, induce the United States to remove their duty; this the Canadian Association think would give them control of the trade. At present Canada exports about 500,000 cords of pulp wood yearly, so that the proposed export duty would, it was said, yield a revenue of 1,000,000 dols. annually. The exporters of pulp wood, of course, object to such an impost. As it is, they have their hands full, they say, to compete with the pulp-wood sellers of Virginia and Maine.

On the face of it, Canada is wise to encourage her own manufacturers. Her exports of the raw material, *i.e.*, pulp wood, practically all of which goes to the United States, have been as follows:—

	Dols.
1890.....	108,998
1891.....	219,458
1892.....	386,092
1893.....	392,262
1894.....	468,359

These figures show a constantly increased export of raw material. The pulp wood exported in 1894 would be capable of producing mechanical pulp to the value of 400,000*l.* sterling, or about five times the value of the pulp wood now exported. If converted into chemical pulp the export value would be no less than 700,000*l.* sterling.

As it is, Canada is doing an increasing export trade in pulp as well as in the wood. The exports of pulp stand thus:—

	Dols.
1890.....	168,180
1891.....	280,619
1892.....	355,303
1893.....	455,893
1894.....	547,217
1895.....	590,874

These figures show also a steady annual increase.

The British demand for wood pulp is largely on the increase. The imports for 1895, for example, were of the value of 1,574,400*l.* (297,098 tons), an increase of 150,000*l.* over 1894.

There is a further stage to which Canadian mills should carry this wood-pulp business, namely, to the stage of paper manufacture. The United Kingdom imported last year unprinted paper to the value of 2,046,106*l.*, and strawboards, millboards, and wood-pulp boards to the value of 548,254*l.* The exports of paper from the United States were last year of the value of about 500,000*l.* sterling. Canada, with her forest resources and unlimited water power, should certainly take her place in the business. At present Great Britain looks chiefly to Germany, Holland, Sweden, and Belgium for her imported unprinted paper.

Esparto Fibre in Tunis. Chamber of Commerce Journal, April 1896, 69.

THE *Handel's Museum*, in an interesting article on esparto fibre, in which it is stated that there are two sorts of this fibre—"rusia," long and firm, and "mahbula," so called from its thread-like character. "Rusia" embraces nine different qualities, one of which, "hemmeima," possesses a long and tolerably thick stalk, used in cigar-making, art-plaiting, and paper-making. The sort known as "lass" is a very fine plant, which, at Marseilles, where it is used for making "seourins" (*i.e.*, mats which in oil factories serve as a basis for the presses), is preferred to all other kinds. The chief markets for esparto in Tunis are Sfax, Gabes, and Skira. For export, it is made up in bundles of about 150 kilos. The Tunis fibre, if in its raw state, pays an export duty of frs. 1.27 c. per 100 kilos., whilst the Tripolis fibre is perfectly free from duty.

PATENTS.

Paper suitable for Writing Purposes, Improvement in or relating to. F. E. Ullstein, Leipzig, Saxony. Eng. Pat. 5657, March 18, 1895.

UNFINISHED but sized paper of a kind suitable for writing paper is converted into imitation leather by means of special embossing rollers, which operate so as to produce on the surface of the paper lines or indentations similar to those found on leather. The material may be varnished with a lacquer similar to that commonly used in the manufacture of artificial leather, such as linseed oil and vegetable wax.—A. G. B.

Peat, The Treatment of; Improvements relating to, and to Apparatus therefor. H. H. Lake, London. Froux M. M. Rotten, Berlin, Germany. Eng. Pat. 6615, March 30, 1895.

A PROCESS for the separation of peat substance into fibres, other vegetable matter, and mud. The peat, suspended in water, enters at the front of a box with transverse partitions of less height than its outer walls, and, passing out at the rear wall of the box, is strained through a sieve of fine mesh. The mud and water passing through are separated in settling tanks; the fibres remain on the sieve, and can be used for paper making; and other vegetable matter is deposited in the partitioned box.—R. B. B.

Paper Pulp [Hypochlorous Acid and Chlorine], Process for Bleaching. F. Stehle, Coeslin, Germany. Eng. Pat. 10,716, May 30, 1895.

FIBROUS pulp, straw pulp, and "more particularly, certain rag sorts," are first partially bleached by means of calcium hypochlorite and chlorine. The pulp is next pressed until

the amount of moisture present in it is reduced to about 50 per cent., when it is placed in a gas-tight vessel and treated with chlorine gas. It is afterwards washed and otherwise treated in the customary manner.—E. B.

Cellulose suitable as a Raw Material for Paper and for other Purposes, Improvements in the Manufacture or Preparation of. A. Dufek and A. Merrel, Prague, Bohemia. Eng. Pat. 24,272, Dec. 18, 1895.

CELLULOSE and paper are manufactured from the roots of the weed *Agropyrum repens*. More than one-third of these roots consists of strong and pliable fibres suitable for this purpose. The cleansed roots are cut into pieces about 1½ ins. long, and are boiled in suitable alkaline liquids under a pressure of, preferably, about 6 atmospheres.—R. B. B.

Woody and Similar Fibrous Substances, in Suspension; Straining. A Process for, and Apparatus therefor. J. A. F. Wallberg, Karlstad, and J. D. Ullgren, Katrineholm, Sweden. Eng. Pat. 2655, Feb. 5, 1896.

A PROCESS for straining wood pulp, &c., which consists in conducting the fibres, suspended in water or other liquid, through a fixed tube or drum composed partially or wholly of sieve plates, and communicating to the liquid, by means of an elastic rod within the tube, an undulating and vibratory motion, so that it is alternately sucked away from and driven against the sieve plates.—R. B. B.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Camphor, Partial Synthesis of. J. Bredt and M. de Rosenberg. Bull. Soc. Chim. 1896, 135—142.

ACCORDING to Wislicenus, when calcium adipate is distilled it yields oxypentamethylene, and on the hypothesis that camphor is made up of two pentamethylene nuclei according to the following formula—

the authors have treated in the same way homocamphoric acid, since this may be considered to have a constitution in the camphor series analogous to that of adipic acid. Homocamphoric acid, obtained by saponifying camphor cyanide, is converted into its calcium salt, $\text{C}_{11}\text{H}_{16}\text{O}_4\text{Ca} \cdot 7\text{H}_2\text{O}$. The salt loses its water of crystallisation at about 140° C., and when distilled in a current of carbonic acid, a syrupy distillate is obtained, which, after drying on a porous plate, forms a greyish-white mass. It is purified by steam distillation, but still contains traces of a yellowish oil, from which it can be freed by pressing between porous plates. The substance then melts at 175° C., and shows all the properties of natural camphor. The yield calculated on the calcium salt is about 70 per cent. of the theoretical.

—T. A. L.

Charas: the Resin of Indian Hemp. T. B. Wood, N. Spivey, and T. H. Easterfield. Proc. Chem. Soc. 1896, [163], 76.

THE authors have examined "charas," the exuded resin of *Cannabis indica*, with a view to the isolation of the active principle. The method adopted consists in the fractional distillation of the ethereal extract prepared from the crude substance. By this means four compounds were isolated:—(1.) A terpene, b.p. 170°—180°. (2.) A sesquiterpene, b.p. 258°—259°, identical with that previously obtained by Valenta from Persone's "cannabene," the green oil obtained when the hemp plant is distilled with water. (3.) A paraffin, probably $\text{C}_{29}\text{H}_{60}$, m.p. 63·5°—64°. (4.) A red oil, formula $\text{C}_{15}\text{H}_{22}\text{O}_2$, semi-solid below 60°, and boiling constantly at 265° at 20 mm. pressure; this compound is present to the extent of 33 per cent. in the sample of charas examined. In doses of 0·05 grm. it produces intoxication, followed by sleep. The substance has also been isolated by the authors from a number of pharmaceutical preparations made from the plant. The resin as prepared by

T. and H. Smith in 1847 contains no less than 80 per cent. of the oil. There can be no doubt that the characteristic action of Indian hemp is due to the presence of the compound.

Camphor, Conversion of Dextro-Camphoric Acid into; Partial Synthesis of Camphor. A. Haller. Comptes rend. 1896, 122, 446.

IN a previous paper (Comptes rend. 1896, 122, 293) is described the reduction of camphoric anhydride to campholid, a lactone analogous to phthalid. Campholid, when heated in a sealed tube with a molecular proportion of pure potassium cyanide at 230°—240° for six hours, is converted into the potassium salt of cyanocampholic acid—

from this, by saponification, homocamphoric acid—

is obtained, the lead salt of which, on gentle heating, decomposes into camphor and lead carbonate. Thus the synthesis of camphor is reduced to that of camphoric acid. The cyanocampholic acid produced by these processes is identical in melting point and rotatory power with that prepared from cyanocamphor by the action of alcoholic potash; the homocamphoric acid is identical with that prepared by direct saponification of cyanocamphor.

—A. C. W.

Formaldehyde, Production of Pure Gaseous. A. Brochet. Comptes rend. 1896, 122, 201—203.

PASSING a mixture of air and methyl alcohol vapour over heated platinum, as a method of preparation, is attended by several disadvantages. Some 5—10 per cent. only of the alcohol burnt is converted into formaldehyde, the remainder undergoing more or less complete combustion to carbon dioxide and water, the latter imparting excessive humidity to the atmosphere. What is more serious, it is found that there is invariably a quantity of carbon monoxide formed (from 3—5 per cent. of the alcohol used). All these difficulties are avoided, according to the author, by preparing the gaseous formaldehyde by passing a current of warm air over solid trioxymethylene, broken up into small fragments; the supply of gaseous formaldehyde in a pure condition thus obtained is easily regulated, and may be applied in sterilising objects which cannot withstand high temperatures. A further advantage is that the unpleasant and clinging odour which is produced by the slow combustion of methyl alcohol is entirely absent, the smell of the formaldehyde disappearing rapidly.—T. E.

Cinchonidine and Homocinchonidine: their Microchemical Distinction. H. Behrens. Zeits. anal. Chem. 1896, 35, 133.

CINCHONINE, cinchonidine, and homocinchonidine are precipitated from a solution of their hydrochlorides by sodium carbonate in the order given; they are distinguished by the different size and shape of their crystals. Cinchonidine and homocinchonidine obtained by sublimation, their chloroplatinates and hydro-iodides, all differ in crystalline form, and the latter base, as also its compounds, always occurs in much larger crystals. Thus homocinchonidine cannot be impure cinchonidine.

By sublimation no quinine or quinidine could be found in cinchonidine, and attempts to prepare the small crystals by fractional precipitation of solutions of mixtures of the large crystals with quinine, quinidine, and cinchonine were without result.

There appear to be two distinct modifications of cinchonidine, of which the large crystalline variety is the more abundant in the preparations examined. The change of one modification into the other, according to the method of Hesse (Ann. Chem. Pharm. 258, 140), could not be accomplished.—A. C. W.

Formopyrine, A New Compound of Antipyrine and Formaldehyde. E. Marcourt. Bull. Soc. Chim. 1896, 15, 520.

AN aqueous solution of antipyrine mixed with a molecular proportion of 40 per cent. of formaldehyde gives, after some

days, a precipitate consisting of a simple addition product, $C_{11}H_{15}ON_2 \cdot CH_3O$, melting at 142° . Heated to a higher temperature, it decomposes, giving the smell of pyrrol. Formopyrine is insoluble in cold water, slightly soluble in boiling, soluble in chloroform, acetic acid, and alcohol. Dilute and strong acids dissolve it, forming stable salts of an intensely bitter and acid taste (except the insoluble oxalate) decomposed by alkalis with precipitation of the base. The reactions of formopyrine are with slight exceptions those of antipyrine.—A. C. W.

"Pyranthin," A New Febrifuge. A. Piatti. Chem. Zeit. 1896, 20, 54—55.

"PYRANTIN" is the name given to the new febrifuge *p*-ethoxyphenylsuccinimide, $(CH_3CO)_2 \cdot N \cdot C_6H_4 \cdot OC_2H_5$, which may be prepared by fusing the hydrochloride of *p*-amidophenetol or phenacetin with succinic acid, and extracting the melt with alcohol. The yield is nearly theoretical. Pyranthin crystallises in colourless prismatic needles, melting at 155° , and insoluble in ether. One part dissolves in 1,317 parts of water at 17° , and in 83.6 parts at 100° . The following are the characteristic reactions of pyranthin:—(1.) By hydrochloric acid or fused hydrogen-potassium sulphate it is split up into succinic acid and *p*-phenetidine, which latter can be identified by means of the ferric chloride test. (2.) If 0.05 gm. of pyranthin be dissolved in 2—3 c.c. of hot concentrated HCl, diluted with water, and one drop of a 3 per cent. solution of chromic acid be added, the liquid turns to a ruby-red. (3.) If fused with potash, and to the aqueous solution of the melt be added some calcium hypochlorite, a red coloration gradually appears.—I. S.

Opoponax. A. Baur. Arch. de Pharm. 233, 209.

ONE of the brands on the market, which has the appearance of a brownish resin, contains: moisture 4.5, woody fibre 70, essence 6.5, and resin 19 per cent. The author has separated three resinous substances from it, which he has termed pana-resene- α ($C_{25}H_{34}O_4$), pana-resene- β ($C_{23}H_{30}O_4$), and pana-resinotannol ($C_{33}H_{40}O_4$). When crude opoponax is distilled with superheated steam an essential oil passes over, whilst the resinous residue contains the above substance, together with a decomposition product, chironol. This substance, which is an alcohol having the formula $C_{28}H_{44}O$, crystallises in fine needles, melting at 176° C., and giving an acetyl derivative melting at 196° C., and, on oxidation with permanganate, an acid, $C_{28}H_{44}O_4$, melting at 108° C. The essential oil consists principally of a mixture of terpenes boiling at 105° — 120° C., of terpenylic ethers, and also of a compound, $C_{30}H_{46}O$, which boils at about 250° — 255° C., and reacts violently with benzoyl chloride. Crude opoponax contains, in addition, an astringent substance and a gum soluble in water. According to the author, Mecca balsam contains a volatile oil distilling at 140° — 170° C., and a resinous substance partially soluble in soda, insoluble in ammonia. It contains alcohols, but not ethers of the resinotannol group. In conclusion, a histological description of plants yielding opoponax balsam is given.—T. A. L.

Sagapenum. Hohenadel. Arch. de Pharm. 233, 259.

SAGAPENUM balsam has the following composition:—Resin soluble in ether, 56.8; essential oil, 5.8; water, 3.5; gum, 23.3; woody fibre, 10.6 per cent. The essential oil can be separated by distillation in a current of steam, and the resin, which is soluble in ether, chloroform, alkalis, and sulphuric acid, and can be sublimed, melts when pure at 74° — 76° C. It does not contain any aldehydic compounds. In order to saponify it, it is necessary to heat it for a very considerable time with dilute sulphuric acid (1 : 3), when it is converted into umbelliferone and sagaresinotannol, $C_{29}H_{40}O_5$. The latter compound on heating with nitric acid (sp. gr. 1.27) on the water-bath yields styphnic acid. The essential oil of sagapenum is yellowish and has a disagreeable odour. Its specific gravity is 0.905, and it contains 9.7 per cent. of sulphur. On fractionation, an ether of valeric acid (hornyl valerate?) can be separated, together with a blue mal-odorous liquid, which has a characteristic absorption

spectrum. Analogous essences, valerian, asafetida, galbanum, &c., on distillation, give similar blue liquids, probably formed in the operation.—T. A. L.

Rhodinol from Oil of Pelargonium and Otto of Roses. P. Barbier and L. Bouveault. Comptes rend. 122, 529—531.

IN a previous communication (Comptes rend. 117, 1092) the identity of the principal constituent of oil of pelargonium with rhodinol from otto of roses was suggested, and this the authors now propose to confirm by a comparison of the chemical properties of the two substances. Rhodinol is, however, certainly different from limonol (geraniol), although this view has been contradicted quite recently by Erdmann and Huth (J. Prakt. Chem.; this Journal, 1895, 292). The confusion has arisen from the fact that oil of pelargonium contains both limonol and rhodinol. The latter can be separated from the mixture by means of its benzoyl compound, and the authors propose that the name rhodinol, which formerly was applied to the mixture, shall now designate the alcohol of the formula $C_{10}H_{18}O$ free from limonol. The alcohol, whether obtained from oil of pelargonium or from otto of roses, has a rose-like smell, boils at 110° C. under a pressure of 10 mm.; its specific gravity is 0.8731 at 0° C.; and $n_D^{20} = -2^\circ 11'$. In a subsequent paper the authors propose to show that the chemical properties of the two alcohols confirm their identity. The proportion of rhodinol in the two oils amounts at most to 20 per cent. (See also this Journal, 1894, 1085).—T. A. L.

Rhodinal, and its Transformation into Menthone. P. Barbier and L. Bouveault. Comptes rend. 1896, 12, 737.

PURE rhodinol, submitted to regulated oxidation by the chrome-sulphuric acid mixture, and the product boiled with water, the distillate being repeatedly fractionated *in vacuo*, gives a liquid boiling at 93° — 95° under 10 mm. pressure. Rhodinal thus obtained has the odour of peppermint; its composition is $C_{10}H_{18}O$; it does not combine with sodium bisulphite, but gives easily an oily oxime, boiling at 130° — 135° under 10 mm., from which the rhodinal is regenerated by dilute sulphuric acid. With the semi-carbazide it gives a crystallised product, separable by solvents into two isomeric carbazones. The first and most abundant is very soluble in ether, and melts at 115° . It dissolves in cold, strong hydrochloric acid, and is precipitated by water without change. Rhodinal is an aldehyde of rhodinol, and the semi-carbazones of the aldehydes are only decomposed by treatment with hot dilute acids, whilst those of the acetones are decomposed in the cold acid. The second semi-carbazone is insoluble in ether, and is an oil smelling of peppermint. It is identified as the semi-carbazone of menthone. Thus, the original liquid obtained by oxidising rhodinol is a mixture of rhodinal and menthone.

Previously, the authors had separated two bodies from essence of pelargonium, to which they assigned the formula $C_{10}H_{18}O$ and $C_{10}H_{16}O$ respectively; but they now recognise that these bodies were isomeric, and identical with those here described.

If the oxime of the mixture of rhodinal and menthone be treated with acetic anhydride, the product is purely, and in theoretical proportion, an acetate of the oxime of the menthone; and the menthone, regenerated by boiling with dilute sulphuric acid, gives only the semi-carbazide melting at 186° — 187° . The isomerism takes place at the moment of treatment by the acetic anhydride, for the oxime, treated by dilute sulphuric acid, regenerates the mixture of rhodinal and menthone.

This isomerism is of great interest, not only in itself, but also because it removes all doubt from the constitution of rhodinol.—E. S.

Citronellal and Rhodinal. P. Barbier and L. Bouveault. Comptes rend. 1896, 122, 795—796.

CITRONELLAL is obtained from citronella oil (from Messrs. Roure, Bertrand, and Son, of Grasse) by distillation under a pressure of 10 mm. of mercury. A colourless liquid boiling at 92° , under 10 mm. pressure, is obtained, the formula of which is $C_{10}H_{18}O$. Its semi-carbazone is characteristic, crystallising in plates which are very readily soluble in all

solvents with the exception of petroleum ether, and which melt at 82°. The aldehyde is converted into citronellal acid by passing through the stages of oxime and nitrile. The acid yields a paratoluide which boils without decomposition at 230° under a pressure of 10 mm., is easily soluble in organic solvents with the exception of petroleum ether, and melts at 95°. The paratoluide of the isomeric rhodinic acid melts at 89.5°. On oxidation, citronellal yields acetone and *β*-methyl adipic acid.—T. E.

Anise, Russian Oil of. G. Bouchardat and Tardy.
Comptes rend. 1896, 122, 198—201.

The oil is cooled to 5° and the liquid part drained off from the solid anethol which forms the major part of it; a repetition of this process at -15° removes a further quantity of anethol and anise-camphor or fenchone. The liquid obtained at +5° is dextro-rotatory whilst that obtained at -15° rotates the plane of polarisation to the left, showing that the oil contains several substances acting in different ways on polarised light. The liquid combines partially with sodium bisulphite, the compound after purification and decomposition yielding an oil which is separated by fractional distillation into fractions boiling from 245°—248°, and from 260°—265° respectively. The first consists of anise aldehyde, $C_9H_8O_2$. It is inactive, smells of dry hay or hawthorn, and has the density 1.141 at 0°. The second has the density 1.095 at 0°, is also inactive, and resembles the first in its odour; dilute potassium permanganate solution oxidises it to anise and acetic acids, it is therefore probably a ketone of the formula $C_{10}H_{10}O_2$. 22 kilos. of the anise oil yielded 80 grms. of the aldehyde and 20 grms. of the ketone, which are probably products of the oxidation of the anethol and estragol contained in the oil.—T. E.

Isosafrol, Synthesis of. C. Mouren. Comptes rend. 1896, 122, 792—795.

ISOSAFROL is synthesised by heating methylene homocaffeic acid—

it is thus proved to be propenyl-methylene-catechol—

the only formula available for its isomer, safrol, being therefore—

PATENTS.

Acetone, Improvements in Processes of and Apparatus for Making Pure. O. Porseh, New York, U.S.A. Eng. Pat. 5255, March 12, 1895.

This invention is designed for producing pure acetone suitable for the manufacture of smokeless powder, for which purpose it must meet the following requirements:—(1.) It must be perfectly clear and limpid. (2.) It must be miscible with water in every proportion, and the mixture should not show a cloudiness even after long standing. (3.) It must be perfectly neutral. (4.) It must indicate at

15° on a thermo-alcoholometer of Schultze (Berlin) at least 99.5 per cent. (5.) It must not contain more than 0.1 per cent. of aldehyde, and its iodometric test should not show less than 98.5 per cent. of C_3H_6O . (6.) On distillation at least 98.8 per cent. should pass over at 58°. The process consists in subjecting acetates in the presence of calcium hydrate in excess at a uniform temperature to destructive distillation and to the action of superheated steam. By this means, an alkaline residue is obtained, which is perfectly free from acetic acid, so that the yield of acetone approaches almost the limit of the theoretical yield, and thereby 25 per cent. of pure acetone boiling at 58° may be regularly obtained from commercial calcium acetate. The acetone vapours are condensed into crude liquid acetone, which is mixed with about ten times its weight of water, and allowed to stand for 24 hours in a cool place. Any tar oils collecting on the surface of the aqueous solution are removed by a decanting process, and the clear mixture of acetone and water is subsequently drawn off from the sediment which has collected at the bottom of the containing vessel. The clear liquid containing the acetone is now submitted to fractional distillation in a dephlegmator for the obtainment of the acetone.

The apparatus comprises a jacketed mixing vessel or retort, the jacket being filled with molten lead, which is kept in this condition by the heat of a suitable furnace surrounding the mixing vessel. Thus superheating of the charge in the retort is obviated, and any variations of temperature during the liberation of the acetone prevented, a product being obtained, which is free from aldehyde and ketones. By the introduction of superheated steam into the retort after about 12 per cent. of the acetone has gone over, the generation of the remaining portions is accelerated, whilst the formation of mechanical impurities, and the passing over of any portion of the charge in the form of powder is prevented. The connecting tubes between the retort and the dust collecting vessel, and between the latter and the condenser can be readily cleaned after each operation by a series of steam pipes, whereby the choking of the tubes and the consequent liability to explosion is prevented. On subjecting the aqueous acetone to fractional distillation, the first and last runnings are collected separately, whilst the intermediate distillate containing from 90 to 96 per cent. of acetone is treated separately so as to permit the removal even of the small percentage of water still contained therein. This is effected in a copper still, provided with a rectifying column. The distillation is so regulated that not more than 150 litres pass over per hour, but even of this distillate, the first 50 litres and the last 50 litres should be set aside as probably containing traces of aldehyde. When the iodometric test shows that the quantity of acetone which has been set aside, being a certain quantity running over at the beginning, and also at the end of one distillation mixed with the same quantity obtained by a second distillation,—contains more than 0.1 per cent. of aldehyde, such acetone is passed in the form of gas through red-hot tubes and then condensed again, so that the ketones boiling at a higher temperature than the acetone are split up.—D. B.

Perfumes, Improvements in the Manufacture of. M. Otto and A. Verley, Paris. Eng. Pat. 6596, March 30, 1895.

The claim is for the use of ozone in oxidising the groups of atoms:— $CH : CH, CH_3$ and $CH : CH : CH_2$ into COH . By means of this process iso-safrol, iso-eugenol, and anethol, all containing the group of atoms $CH : CH : CH_3$, may be oxidised to heliotropin, vanillin, and aubepin respectively. The gaseous ozone is allowed to act on the substances (preferably warmed) without using any solvent, thus facilitating the isolation of the products. The following equation represents the typical reaction which occurs:—

Substances which contain the group of atoms $CH_2 : CH : CH_2$, such as eugenol, safrol, and estragol, also yield aldehydes, those named giving vanillin, heliotropin,

and anebpin respectively; the reaction in the case of eugenol is represented by the equation:—

—T. E.

Perfumes, Improvements in the Manufacture of. M. Ekenberg, and Lars Montén, Stockholm. Eng. Pat. 15,592, April 1, 1895. (Under International Convention.)

THE claim is for a process for imparting a greater intensity of odour to perfumes by saturating them with some substance which is wholly or partly gaseous below 30°C ., and which is inodorous or possesses only a faint odour. Further claims are that the pressure developed by the volatile substances within the bottles may be conveniently employed for forcing the perfume out of them and spreading it. The volatile substances may also be used as solvents for the perfume, thus ensuring its perfect vaporisation.—T. E.

Musk, Artificial; Improvements in its Manufacture. H. H. Lake. From the Fabriques de Produits Chimique de Thann et de Mulhouse. Eng. Pat. 10,946, June 1, 1895.

THE manufacture of artificial musk by the nitration of symmetrical (1.3.5) halogen butyl toluenes is claimed. Symmetrical bromobutyl toluene, for example, is prepared by the gradual addition of 1 part of AlCl_3 to 4 parts of meta-bromotoluene and 4 parts of butyl chloride, without application of heat. The reaction being at an end, the mass is poured into water and the crude oil submitted to fractional distillation. The (1.3.5) bromobutyl-toluene boiling between 230° and 250° (or after further purification between 243° and 246°) is then slowly brought into a well cooled mixture of fuming nitric and sulphuric acids, which is finally heated on the water-bath until a sample solidifies at once on pouring into water. The tri-nitro derivative thus obtained forms, after crystallisation from alcohol, yellowish-white needles melting at 129° and possessing a strong odour of musk.—T. E.

ERRATUM.

XXI.—PHOTOGRAPHY.

PATENT.

Photographic Printing Paper and the like; Improvements in and connected with. F. Hrdliczka-Csizsar, Vienna. Eng. Pat. 9438, May 13, 1895.

THE inventor describes the manufacture of a sensitive paper with which, he asserts, it is "possible to obtain good prints with high lights . . . even from the duller negatives, which cannot be reproduced by the processes at present resorted to." It appears to consist essentially in the addition of a small quantity of a chromate (neutral or acid), or of a "compound of ferric cyanates" in dilute alcoholic solution to an ordinary citro-chloride emulsion of silver in "celloidin" or gelatin.—F. H. L.

XXII.—EXPLOSIVES, MATCHES, Etc.

Explosives, Safety. Winkhaus. Trans. North of Eng. Inst. Min. and Mech. Eng. 1896, 45, 141—154.

THE results of the Prussian Fire-damp Commission experiments in 1885 (see also this Journal, 1892, 179) led to the conclusion that high explosives, if fired with a sufficiently strong detonator, explode without igniting either coal-dust or pit-gas (see this Journal, 1889, 415). Lohmann in 1887 found, on the contrary, that with larger charges, all the high explosives were unsafe (see also this Journal, 1889, 419). Safety powders are now made either by reducing the explosion temperature of the substance, by mixing it with a heat absorbent, such as damp sawdust, soda crystals, magnesium sulphate, ammonium carbonate, &c. (as in "Wetter-dynamit"), or by using explosives which have *per se* a low detonation temperature. In the latter group are explosives of the securite class, containing ammonium

nitrate mixed with nitro derivatives of aromatic hydrocarbons, or with non-nitrated carbonaceous substances; to this order belong most of the explosives described in a table which is given.

Lohmann defines as safety explosives all such as prove on experiment to be considerably safer than ordinary dynamite, and have not, in practical mining, produced the ignition of fire-damp; and, in any case, they are deemed sufficiently safe if an unstemmed shot, fired from the steel cannon with 8·82 ozs. of the powder, is found incapable of igniting the coal-dust (from the König pit) in suspension in the experimental gallery at Neunkirchen. But the writer urges that these galleries should be used only for the comparison of explosives, for there is a great difference between a shot fired from a steel cannon and one fired from a bore-hole in a non-conducting material like coal, which, moreover, readily yields a highly inflammable dust; and explosives which have passed Lohmann's test have failed in practice (see also this Journal, 1890, 214). In a table are incorporated the results of the author's experiments with the various explosives employed in Westphalia. Increasing charges were fired until ignition of the suspended coal-dust in the gallery ensued. With three exceptions (noted) no ignition was observed with a charge of 17·64 oz. The shots were fired, unstemmed, from a steel mortar with a 2·16 in. bore, set at an oblique angle in the floor of the gallery.

It is found that, with very safe powders, the paraffined cartridge cases (used when deliquescent ingredients are present) are not dangerous, but when the detonation temperature is high, a plain case is preferable, at least for unstemmed shots. The combination of relative safety with a high shattering power is a characteristic of the new ammonium nitrate powders. Another table given, shows that the safety of these powders diminishes as the percentage of the carbon-bearing constituent is increased; and any degree of safety may be secured by proportioning the ingredients correctly within the practical limits of blasting efficiency and transmissibility of the explosion from one cartridge to another. In the table the results with various mixtures of dinitro-benzene and ammonium nitrate are recorded.

Owing to the hygroscopic character of ammonium nitrate, powders containing this substance occasionally fail to detonate. The addition of 2·5 per cent. of potassium bichromate to Dahmenite has vastly increased its safety without affecting its shattering power; this is due to the readiness with which the bichromate decomposes at a dull red heat, whereby the detonating capacity and rapidity of ignition are increased, whilst heat is absorbed. The addition of 4 per cent. of potassium permanganate to roburite allows the nitrobenzene to be reduced to 7 per cent., and thus great safety is ensured, whilst the blasting efficiency (per unit of nitrobenzene) is not reduced.—W. G. M.

Explosives (Flameless) Committee, Report of the. North of Eng. Inst. Min. and Mech. Eng., Parts I. and III., 1894 and 1896.

THE third and last part of the report of the Committee appointed in 1888 is now published, and the experiments, which are fully described in 136 pages, have led to the following conclusions:—(1) The high explosives tested (amonite, ardeer powder, bellite, carbonite, roburite, securite, and westfalite) on detonation produce evident flame. (2) They are liable to ignite inflammable mixtures of air with fire-damp or coal-dust, or of the three together, and are not absolutely safe when used in presence of such mixtures; but (3) they are less liable than blasting powder to produce such ignition. (4) The ignition of mixtures of air and coal-dust, with or without fire-damp, can be obtained with a much smaller proportion of coal-dust than was previously deemed necessary. (5) The risk of explosion in a mine is lessened, but not abolished, by the use of high explosives in place of blasting-powder; and therefore (6) examinations of the working places, and precautions similar to those in force in mines where blasting-powder is used, must be rigidly observed where a high explosive is employed. (7) In view of the changes from time to time made in the proportions and constituents of

high explosives, it is desirable that the name of the explosive should be printed on the wrapper of each cartridge, and that the date of manufacture, and the proportion of the ingredients used in the manufacture of the explosive should be printed on the case of each packet of cartridges. (8) As these explosives alter in character if improperly kept, every care should be taken in the storage to ensure their being maintained in good condition.—W. G. M.

Smokeless Powder and Manufacture of Same, An Improved.
E. Ungania, Imola, Bologna, Italy. Eng. Pat. 12,325, June 25, 1895.

THE powder is designated "Fulgor" and its chief constituent is nitrated hydrocellulose. The following compositions by weight are given:—Fulgor "A," for military purposes, 100 parts of "hendeka-hydronitrocellulose," 2 of paraffin, 30 of hexa-nitromannite, 0.05 of aniline black; Fulgor "B," sporting powder, 100 parts of "hendeka-hydronitrocellulose," 0.05 of potassium ferrocyanide; Fulgor "C," sporting powder of moderate strength, 80 parts of hepta-hydronitrocellulose, 20 of hexa-hydronitrocellulose, 15 of potassium chlorate, 8 of barium nitrate, 1.50 of paraffin, and 0.05 of potassium ferrocyanide.

To produce "hendeka-hydronitrocellulose" 1 part of hydrocellulose is treated with 20 parts of an acid mixture containing 5 parts of nitric acid (1.52 sp. gr.) and 15 parts of Nordhausen sulphuric acid. The hepta-hydronitrocellulose is made with the following proportions: 1 part of hydrocellulose, 4 parts of nitric acid (42 B.) and 12 parts of sulphuric acid (66° B.). In all the above the proportions are by weight.

The nitro-mannite must not be made by the Stecker process, but by treating very finely divided mannite with a mixture of fuming nitric and sulphuric acids. This, it is stated, will give a nitro-mannite unalterable by heat or light. Powders "A" and "B" are gelatinised by means of acetic ether, and "C" by means of acetone and "benzine."—R. B. P.

Explosives [Nitroglycerin] for Blasting Purposes and for Use as Ammunition, Method of Manufacturing.
R. Weigel, Domitz-on-the-Elbe, Germany. Eng. Pat. 23,242, Dec. 4, 1895.

THIS invention relates to explosives containing nitroglycerin, and has for its object the diminution of the danger attending their manufacture and use. This is stated to be effected by the addition of "erosote and other alkylated, i.e., methylated, ethylated, &c. derivatives of the benzene and phenol class" which lower the freezing point of nitroglycerin, and render the finished explosive "absolutely flameless" capable of being stored in a damp atmosphere, "uninflamable," and insensitive to shock. The following composition is given as a type:—27 per cent. of nitroglycerin, 1 per cent. of collodion cotton, 4.5 per cent. of erosote, 5.5 per cent. of bicarbonate of soda, 53 per cent. of nitrate of soda, 9 per cent. of rye-flour.—R. B. P.

Explosives, Production of, from Reduced and Nitrated Cellulose Bodies. W. Theodorovic, Vienna, Austria. Eng. Pat. 949, Jan. 11, 1896.

THE inventor proposes a mixture of nitrated cellulose, the cellulose, previous to nitration, being first reduced to a pulverulent state by boiling with dilute hydrochloric acid, and "nitrate salts or carbonaceous material," the mixture then being gelatinised by means of amyl acetate and acetone, the gelatinising agent being subsequently removed by treatment with dilute methyl or ethyl alcohol.—W. M.

Explosives, Manufacture of, An Improved Process and Apparatus for. H. H. Lake, Middlesex. From Fried. Krupp, Grusonwerk, Magdeburg. Eng. Pat. 2575, Feb. 4, 1896.

THIS specification describes an apparatus for, and "method of manufacturing tubular or other threads or cords of explosive material from a pasty or plastic mass previously rolled in the form of a band; the said process or method consisting in placing the coil of plastic material in a chamber, and compressing the same throughout its convolutions by forcing a mandril into the central or inner convolution,

thereby displacing the air confined between the convolutions and forcing the material through a die in the form of a thread or cord; or when a hollow tube of the explosive is to be formed a mandril is fixed in the die."—W. M.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Pyrometer, Le Chatelier's. W. C. Heräus. Zeits. f. Elektrochem. 2, 276—277.

A FORM of Le Chatelier's pyrometer, adapted for technical purposes, by W. C. Heräus of Hanau. The thermo-element consists of wires of platinum and of platinum-rhodium alloy, each $1\frac{1}{2}$ metres long and 0.6 mm. diameter, welded or

Fig. 1.

Fig. 2.

firmly joined mechanically at the hot junction, insulated from one another and protected from the fire-gases by porcelain and metal tubes. A modification of D'Arsonval's galvanometer is supplied with the instrument, reading on a double scale either E.M.F. in volts, or temperatures of the hot junction, from 0 to 1600°. Special forms of the instrument are made for special purposes. Rules are given for its use.—J. T. D.

Hydrometer, A New. L. X. Vandevyver. J. Phys. 1895, 4, 561.

THIS hydrometer is so constructed that when the lower compartment B is filled with distilled water, and the stopper D inserted, the instrument will sink to the mark 1.00 when immersed in distilled water. On replacing the water in the

compartment B by the liquid, the density of which is to be determined, and again placing the instrument in distilled water, the desired specific gravity may be read off on the

scale. This hydrometer gives accurate readings to the third decimal, and even the fourth is approximate.—A. K. M.

Assay Balance, An Auxiliary. Proc. Chem. Soc. 1896, [163], 75—76.

This paper describes a new form of balance applied to bullion assaying, the object of which is to give the weight of the gold "cornet" with sufficient accuracy to enable the assayer to put the correct weight in the pan of the ordinary assay balance, and to decide the remaining fractions by means of the rider alone. This auxiliary balance is of such dimensions as to be easily accommodated in the case of the ordinary assay balance. The advantages claimed are—

(1.) Saving of time in weighing, when gold of varying finenesses is under assay. (2.) Reduction of the wear in the weights. (3.) Increased life for the ordinary assay balance. (4.) Avoidance of much of the concentrated attention which tends to make the assayer's work monotonous.

PATENTS.

High Temperatures, Improved Method and Apparatus for Determining. J. G. Wilborgh, Stockholm, Sweden. Eng. Pat. 6284, March 26, 1895.

This specification describes an apparatus "based on the principle that if an explosive substance which explodes at a definite temperature t' be enclosed in a solid body of temperature t , and this body be exposed to a higher temperature T , then the explosion of the said substance will occur after the lapse of a definite time, the length of which will depend on the explosion temperature t' of the substance, on the distance of the said substance from the surface of the body, and on the difference between the temperatures T and t ." The apparatus may be calibrated by means of an air pyrometer and from the calibration an equation may be obtained, which would allow of the measurement of very high temperatures. The explosive is enclosed in a refractory material, and of course a "thermophone" is destroyed each time an observation is made.—W. M.

Oleaginous Materials, A New or Improved Testing Machine for. G. Mitchell, London. Eng. Pat. 16,571, Sept. 4, 1895.

This is an apparatus for testing the amount of oil which can be expressed from a known quantity of material. It consists of a steam-jacketed cylinder fitted with a ram of 1 sq. in. area, worked by a compound lever, at the end of

which is placed a spring balance, which enables the operator to observe what pressure is on the ram; this would be 2 tons when the spring balance registers 112 lb.—J. J. K.

INORGANIC CHEMISTRY.—QUALITATIVE.

Ammonium Sulphide, Replacement of, in Qualitative Analytical Methods. N. Tarugi. Bull. Soc. Chim. 1896, 16, 670. (Original in Gazz. Chim. Ital. 25, 478.)

AMMONIUM thioacetate forms sulphides with cobalt, nickel, manganese, and zinc, but the decomposition of the thioacetate and subsequent precipitation of the sulphide is not complete. The following method is proposed. The filtered liquid after precipitation with ammonia and ammonium chloride is boiled to drive off ammonia, slightly acidified with hydrochloric acid and slight excess of ammonium ferrieyanide added. This precipitates ferrieyanides of cobalt, nickel, and manganese. The filtrate made alkaline by ammonia throws down barium, calcium, and strontium on addition of ammonium carbonate. In the filtrate, ammonium phosphate precipitates magnesium, and finally on adding acetic acid, zinc is obtained as ferrieyanide.

The ammonium ferrieyanide precipitate is shaken with ammonia and filtered, and from the filtrate nickel ferrieyanide is obtained on acidifying. In the residue cobalt is detected by the bead, and manganese by nitric acid and lead peroxide.—A. C. W.

Cobalt, New Compound of, and a Rapid Method of detecting Cobalt in presence of Nickel. R. G. Durrant. Proc. Chem. Soc. 1896, [164], 96.

The author shows that if excess of sodium or potassium bicarbonate be added to a solution of any salt of cobalt, and then hydrogen peroxide, a green liquid is formed.

This liquid appears to contain a cobaltate or cobaltic acid, H_2CoO_3 , for, although the substance has not at present been isolated, volumetric determinations show that the maximum green colour is reached when the molecular proportions of the cobalt salt and hydrogen peroxide are as 1:2; a probable reaction is—

The green solution may be formed in presence of nickel salts, and the reaction serves as a ready method both of detecting cobalt, even in presence of large excess of nickel, and of detecting nickel in presence of considerable excess of cobalt.

Nessler Reaction, its Application for the Detection of Mercury and of Iodides. G. Deniges. Chem. Zeit. 1896, 20, 70.

By suitable modifications, the Nessler reaction may be made use of for the detection either of mercury or of iodides. For the detection of mercury, 2 c.c. of the solution are mixed with 2 c.c. of ammonia and 2 to 10 drops of a 20 per cent. solution of potassium iodide. If the solution remain clear, the addition of caustic alkali will bring about the Nessler precipitate should mercury be present. If there be a white precipitate, this will not appreciably interfere, but if a coloured precipitate be formed, it should be removed by filtration, before the addition of the caustic alkali. The reaction can be used for the detection of the smallest quantities of mercury.

For the detection of iodides, any metals which might interfere should be precipitated by ammonium sulphide; the filtrate is then acidulated with hydrochloric acid, boiled to expel hydrogen sulphide, and saturated with ammonia. Some caustic alkali and a few drops of mercuric chloride are next added, and if a red precipitate be produced, an iodide is present. The reaction is very sensitive, and can be used also in the case of insoluble iodides.—A. K. M.

Chlorates, A specific Colour Reaction for. G. Deniges. J. Pharm. Chim. [6], 2, 400.

The presence of chlorates in solution, when not exceeding 2 per cent., can be detected by the green coloration (also decidedly manifested in the case of 1 mg. of these salts) produced by adding five drops of a 1 per cent. solution of resorcinol, acidified by 10 drops of sulphuric acid, to one or

two drops of the solution under test, previously shaken up with 2 c.c. of pure sulphuric acid, and cooled. After the resorcinol is added, the mixture is again cooled and agitated.

—C. S.

Molybdic Solution as a Reagent. M. G. Meillere.

J. Pharm. Chim. 1896, 6, 3, 61.

The solution of ammonium molybdate usually prepared as a reagent is unstable and not to be relied upon. The author recommends the following prescription for a preparation said to remain good for several months. 200 c.c. of a 15 per cent. solution of ammonium molybdate are mixed with 20 c.c. of dilute sulphuric acid (1:1 by volume), and 30 c.c. of pure sulphuric acid are added thereto. The reagent thus prepared is very sensitive, and can be heated to 100° C. for a short time, a quality favouring the detection of traces of phosphoric and arsenic acid. In cases where the sulphuric acid is not objectionable, the same reagent can be used for quantitative separations. For this purpose gentle warming suffices, the liquid being then allowed to stand in the cold. Precipitation is complete after 12 hours. No tangible quantity of molybdic acid comes down. Complete precipitation of arsenic acid requires longer warming. In spite of the relative stability of the reagent, it is difficult to hit the point when the arsenic acid is completely precipitated and the molybdic acid begins to come down. Should precipitation of the molybdic acid begin to occur, it can be retained in solution in the subsequent conversion of the arsenic acid into ammonium magnesium arsenate, by the addition of a sufficient amount of an alkaline citrate. The tartrate is not to be recommended, as it considerably delays the separation of the precipitate.—B. B.

**INORGANIC CHEMISTRY.—
QUANTITATIVE.**

Hydrofluoric Acid, Note on the Preparation of Pure, for the Analysis of Silicates. A. H. Allen. Analyst, 21, 87.

HYDROFLUORIC acid for use in the analysis of silicates should be free from fixed impurities. The following is a simple method of preparing the pure acid at the time and in the quantity required:—

A mixture of about equal parts of commercial hydrofluoric acid and strong sulphuric acid is placed in a large platinum crucible. Inside this large crucible and preferably supported on a disc of plaster of Paris, or on a leaden ring, is placed a smaller one containing a weighed quantity of the silicate moistened with three or four drops of strong sulphuric acid. The larger crucible is then covered with a platinum dish filled with cold water. The arrangement is then heated, and the hydrofluoric acid is volatilised, and condenses on the bottom of the platinum dish, from whence it drops on to the silicate in the inner crucible. When about 10 c.c. of distillate has collected, the inner crucible is removed, the contents evaporated off, and the whole process repeated once or twice, to ensure complete decomposition of the silicate.—A. S.

Analysis, Electrochemical Methods which can be usefully applied. B. Neumann. Zeits. f. Elektroch. 2, 231—235, 252—260, 269—272.

A BRIEF history of the discovery and development of electro-deposition of metals and its application to their determination is given. The solution from which the metal is deposited should be one which ordinary treatment yields, the deposited metal should be coherent and easily washed, and variations in the current, within reasonable limits, should not affect its consistency.

From solutions containing more than one metal, a mixed deposit is liable to be thrown down. Separations, however, can be effected by (1) depositing one metal at the cathode, whilst the other is thrown down as peroxide at the anode; (2) preventing the deposition of one or more of the metals by addition of excess of strong acid, by conversion into a higher state of oxidation, or by addition of excess of alkali, and formation of complex compounds; (3) by regulating

the electro-motive force. In practice only the first two plans are really available, and in many cases it is most advantageous to make a separation by chemical means, and then to deposit each metal from a pure solution.

At the cathode come away hydrogen and metals. At the anode separate oxygen, the halogens, sulphur, and other bodies, of which only oxygen (in the form of peroxides) and the halogens need be considered. The halogens can be determined (Vortmann) by using a silver anode in a tartaric acid solution, and finding the increase of weight of the electrodes (both, for silver may go into solution from the anode and be deposited on the cathode), and the author has determined fluorine similarly; but the amounts which can be dealt with in this way are very small, and no separation of the different halogens is possible. Many metals appear at the anode as peroxides, but in most cases the metal itself is simultaneously deposited at the cathode, so that the only metals practically determinable as peroxides are lead and manganese.

Individual metals are then considered, copious references to original authorities being given.

Manganese.—The electrolytic determination of manganese presents no advantage over the ordinary volumetric or gravimetric methods.

Lead from neutral solutions deposits both as metal and peroxide. From neutral acetate solution, solutions with free acetic acid, solution in saturated sodium chloride, or in excess of sodium hydroxide with or without addition of alkaline tartrates or acetates, solution in ammonium oxalate, in pyrophosphoric acid, or solutions containing easily oxidisable bodies, it falls as metal alone; but the process is not suitable for analysis, for the deposit is not firm or coherent, and, moreover, often forms a short circuit between the electrodes. The deposition as peroxide alone, however, is very satisfactory; this takes place from a solution containing at least 10 per cent. of nitric acid. The deposit is coherent at the ordinary temperature or up to 60°—70° C.; at higher temperatures it is apt to peel. The current density should be 1—2 amp. per 100 sq. cm., the E.M.F. 2.3—2.7 volts. The author has deposited in one hour, from a strong solution, at the ordinary temperature (1 amp. per 100 sq. cm., 2.3 volts), 4 grms. of perfectly coherent peroxide. Dilute solutions need a longer time to deposit an equal quantity. The analysis of galena affords an illustration of the application of electrolytic methods; here the lead, coming to the anode, is separated from most associated metals. The ore is dissolved in nitric acid, diluted, filtered, and electrolysed; lead alone appears at the anode; copper, antimony, gold, mercury, may deposit at the cathode; other metals remain in solution. Bismuth, if present, may, in part, come down with the lead, but not silver, if enough nitric acid and a few drops of oxalic acid solution be present. The peroxide must be dried at 180°—190° C.

Of metals deposited at the cathode are to be considered:—

Iron.—This can only be deposited from solutions of complex salts, and the ordinary methods for its determination are so accurate, that the electrolytic method presents no advantage.

Cadmium can be deposited from neutral or ammoniacal solutions, solutions in potassium cyanide, or various alkaline salts. The separation of cadmium from other metals is not practicable electrolytically, and gravimetric methods are, on the whole, to be preferred.

Cobalt and Nickel.—These two metals behave practically alike in their electrolytic relations. They are completely deposited from neutral solutions to which has been added a very small amount of acetic acid, or excess of alkaline tartrate, citrate, or oxalate, or potassium cyanide. The usual method is to electrolyse a solution of the sulphate, to which ammonium sulphate and excess of ammonia have been added. Ohl adds, for 0.1—0.15 grm. of nickel as sulphate, 6—9 grms. of ammonium sulphate, and 2.5—4 grms. of ammonia; but the author finds that the proportion of nickel may be increased tenfold without injury. With 0.5—1.5 ampère per 100 sq. cm., 2.8—3.3 volts at ordinary temperatures, 2 hours suffice to deposit the nickel from 1 grm. of even rich ores or alloys. Attempts to use the chloride as a depositing solution have proved unsatisfactory. In the

analysis of ores, metals of the copper group can be precipitated by hydrogen sulphide or deposited electrolytically from an acid solution; excess of ammonia then precipitates iron, manganese, and aluminium, and the nickel or cobalt can then be deposited, free from every metal save zinc, which, if present, could be precipitated from acetic solution by hydrogen sulphide. To separate cobalt from nickel, Vortmann uses a solution with alkaline tartrate, large excess of sodium hydroxide and some potassium iodide, from which, with currents up to 1 ampère per 100 sq. cm., cobalt alone separates. Nickel and cobalt may well be determined electrolytically, especially as the chemical methods are troublesome and not very accurate.

Zinc.—Does not deposit from strongly acid solutions, and from neutral solutions comes down in a spongy condition. Addition of small amounts of acetic acid, ammonium oxalate, ammonium or sodium acetate, or ammonium phosphate improves this; good deposits are also got from a solution with excess of sodium hydroxide or of potassium cyanide. The deposited zinc adheres strongly to the platinum cathodes, which should therefore be coated with silver or copper. The process is slow (2 hours for 0.15–0.2 gm., with 1–1.5 amp. per 100 sq. cm.), and the current density must be well kept up towards the end, or the last traces of zinc fail to deposit. Separation of zinc from other metals must be done chemically, and on the whole the balance of advantage is on the side of chemical rather than electrolytic methods.

Gold.—Deposits readily from neutral solutions, from the double chlorides of gold and alkali metals, from solutions in potassium cyanide, sodium sulphide, &c. But the deposit is often pulverulent and the amount which can be deposited in a coherent state is very small. The electrolytic method is not advisable for ordinary purposes.

Bismuth.—Almost impossible to separate bismuth electrolytically from other metals.

Arsenic.—Is only very incompletely precipitated from neutral, not at all from acid solutions.

Silver.—Behaves like bismuth. Gravimetric methods are to be preferred.

Mercury.—Can be completely deposited from neutral or slightly acid solutions, solutions with excess of potassium cyanide, sodium sulphide, or ammonium oxalate or tartrate. For separations chemical methods are preferable.

Copper.—Deposited from sulphuric or nitric acid solutions with not too much free acid; from hydrochloric acid solutions is not coherent unless sodium chloride, ammonium chloride, or sodium acetate be added. Ammoniacal solutions can also be used, if sufficient ammonium nitrate be present. Solutions with excess of potassium cyanide, or of alkaline phosphates, oxalates, tartrates, or formates are also available, but in practice only the solutions in nitric or sulphuric acid are used. Copper is in this way separable from iron and the other metals which do not deposit from acid solutions, and (in nitric acid solutions) from lead; not, however, from silver, bismuth, mercury, tin, arsenic, or antimony. From these separation by chemical means is to be preferred, but as in many natural products few or none of these occur, the electrolytic determination of copper is very practicable and largely used. In a solution with 8 per cent. of free nitric acid, the current density should be 1–2 amp. per 100 sq. cm., E.M.F. 2.2–2.7 volts, and temperature, 50°–60° C. Stronger currents may be used, but the amount of copper deposited does not increase proportionately. A solution in sulphuric acid with 3 per cent. of free acid corresponds to the nitric acid solution mentioned.

Antimony.—Deposits from solutions in hydrochloric acid, sodium or ammonium chloride, with or without addition of alkaline tartrates or oxalates. The cathode should have a dead surface, or the deposit is not coherent. The deposition from the chloride is rapid. Tartaric acid solutions give good deposits, but are too slow. The most available is a solution of the sulphide in sodium monosulphide. With a solution containing sodium sulphide of 50–70 per cent. of saturation, 1–2 amp. per 100 sq. cm., and E.M.F. 1.5–3 volts, the process proceeds at the ordinary temperature or at higher temperatures, more rapidly in the latter case (at 60°–80°, 0.3–0.4 gm. antimony in 1½–2 hours). The preparation of the solution

of the sulpho-salt separates the antimony from all other metals save arsenic and tin; the arsenic can be volatilised previously as chloride, converted into arsenic acid, or dissolved as sulphide by ammonium carbonate, whilst tin does not deposit from strong solutions of sodium sulphide. This plan, then, is of very general use in determining antimony.

Tin.—Solutions of stannous and stannic chlorides, or other salts to which hydrochloric acid has been added, are available; also with excess of sodium hydroxide or potassium cyanide, or ammonium oxalate and oxalic or acetic acid. It deposits best from solutions of the sulphide in ammonium sulphide (from weak sodium sulphide solutions very imperfectly, from strong ones not at all). If tin be already in the form of dioxide, it is best weighed straight off; but if we have the sulphides from which arsenic and antimony have been separated as just described, 20–25 grms. of ammonium sulphate are added to the solution, and heated for 10–15 minutes, then a current of 1–2 amp. per 100 sq. cm. and E.M.F. 3.3–4 volts used; at 50°–60°, 0.3–0.4 gm. tin will deposit per hour, with 1 amp. per 100 sq. cm. Tinstone, fused with sodium carbonate and sulphur, gives a solution which can be directly used for electrolysis.

Storage cells form by far the most suitable source of current for this work; where there is no dynamo they can be charged by a thermopile, or by a number of primary cells. A Gülicher thermopile, failing secondary cells, is also a useful source of current, and enables any constant E.M.F. between certain limits to be maintained.

Electrodes are always of platinum and are of two types. In one the cathode is a slit hollow cone or cylinder pierced with holes, and the anode a spiral wire; in the other the cathode is a shallow dish or basin and the anode a horizontal disc.—J. T. D.

Platinum, The Assay of. E. H. Miller. School of Mines Quarterly, 17, 26–38.

AFTER describing and comparing the methods of Berzelius, Gibbs, Deville and Debray, and Perry, and giving results of experiments showing the impossibility of obtaining accuracy whilst employing small quantities in the assay of poor ores, the author suggests the following method of procedure:—

1 gm. of platinum alloy is mixed with test lead and scorified at a high temperature until covered over, poured, and the button, which should weigh about 12 grms. and be malleable, hammered to detach slag. The button is treated with 200 c.c. of nitric acid (sp. gr. 1.08) until the action ceases, and is then filtered and washed with water. The paper containing the residue is burned in a porcelain capsule and then transferred to the muffle and ignited for 10 minutes with the door open. After cooling, it is heated to boiling with nitric acid (1.08) for several minutes washed, ignited, and weighed. The weight is that of the gold, platinum, iridium, and iridosmium. The finely-divided metal so obtained is then warmed with dilute aqua regia (1:3) for a few minutes, which readily dissolves the gold and platinum and leaves the iridium and iridosmium to be filtered off, washed, and weighed together. The iridium is then dissolved out by treatment with strong aqua regia and the iridosmium weighed alone. The gold and platinum are separated by oxalic acid. The solution containing them is evaporated just to dryness to remove all the nitric acid, then dissolved in water and a few drops of hydrochloric acid, and the gold precipitated by warming with oxalic acid and allowing to stand for half an hour. After filtering, the gold is cupelled with silver to remove filter ash and any traces of platinum, parted and weighed. The platinum is precipitated by ammonium chloride after destroying the oxalic acid.

By this method the iridium is separated from both the platinum and iridosmium, the gold result is as accurate as by the wet method, and the platinum result is nearly so. The platinum is equally well determined in any material, from a low grade ore to platinum foil. In the former case the platinum from four to six assay tons is collected by a preliminary treatment in a lead button of about 20 grms., which, after scorification, is a convenient size for assaying

by nitric acid. The ratio of lead to platinum should be 30:1 to obtain a malleable button from which the slag can easily be detached, and the quantity of ore to be taken should be at least 30 grms. in the case of poor Russian ores.—A. W.

Cement, Hot Tests for. L. Erdmenger. Thonind. Zeit. 1896, 20, 2.

THE author discusses the mechanism of the changes which occur when cement test pieces are subjected to hot tests, boiling tests, and his own high-pressure steam tests. He points out that the increased rapidity and intensity of the changes occurring during hardening, which is brought about by tests of this class, may result in an increase of strength or in complete destruction or in some intermediate condition, according to the quality of cement. Cements which are not unexceptionable when tested by these methods generally show improvement after they have been aerated by exposure, although the like treatment may lower the strength as determined by ordinary cold tests. The opinion that the destruction of test pieces exposed to boiling water or the like is due to the presence of anhydrous calcium sulphate, rather than to that of free lime, receives no confirmation from the author's experiments.

—B. B.

Cement Testing. C. Berger. Mitt. k.k. Tech. Gewerbe-Museums (Vienna), 1896, 57—81.

THE paper consists of an account of a considerable number of tests made by the author on samples of Portland and Roman cement. That part not concerned with routine methods of testing is embodied in the following excerpts:—

In general, the tests were made according to the standard methods current in Austria, but an exception is made in respect of tests for constancy of volume, which on account of the short time available, were of the "rapid" class. The rise of temperature occurring on gauging cement with water was also determined, the increase of temperature in the case of Portland cement varying from 1.6 to 11.1 °C., but rarely exceeding 10° C. Seeing that the rise of temperature is largely dependent on the rate at which the reactions concerned in the first setting of the cement occur, an exact correlation between the rise of temperature, and the presence of unsaturated lime in the cement cannot be arrived at. Thus, cements which are perfectly constant in volume and undoubtedly sound may give a rise of temperature as great as, or greater than, that given by cements which have a marked tendency to "blow." It may be noted incidentally that Portland cements may show a rise of temperature of 1.4—2.5° C. before any indication of setting can be discerned. Some relation can be traced between the initial setting and the rise of temperature of a cement, for both phenomena are plainly dependent on the beginning of chemical change of certain of the cementitious constituents. The determination of the initial set is of practical importance, inasmuch as it is undesirable that cement should be worked or handled after this has begun. With regard to the specific gravity, the limits observed for Portland cement were 2.96 to 3.23. Comparative tests were made for tensile strength of cement which, after setting, had been kept in the one case in water and in the other in air, and it was found that in general, cement kept in air had a higher tensile strength at a given date. The difference was most marked with overlined cements, which remained sound in air but were weakened by being kept under water. The question of aeration of cement before use is considered by the author, who shows that in many cases an improvement as to strength takes place on keeping, especially if the cement was originally somewhat overlined. A decrease of strength, on the other hand, is not infrequently observed, particularly in test pieces which have been kept in the air, instead of under water, with cements which are not unduly rich in lime.

It may be noted that a considerable increase in tensile strength may result from the exposure of the test piece first under water and then in air, the figures quoted in one case being greatly in excess of those given by the same cement kept either in air alone or in water alone. The rapid tests used for determining the constancy of volume

of Portland cement, that is, its freedom from tendency to blow, are as follows:—

(1.) *The Steam Test* in which a pat of cement after 24 hours setting in moist air is placed in a double-walled vessel, the outer part of which is filled with water and heated until steam is evolved and penetrates to the inner vessel, the heating of the pat thus effected being continued for four hours.

(2.) *The Boiling Test.* Balls of the cement 4—5 c.m. in diameter are allowed to set for 24 hours in moist air and are placed in water, which is brought to the boil in the space of about 30 minutes, and kept boiling for six hours.

(3.) *The Firing Test.* In this, two balls similar to those used in test No. 2 are allowed to become fully set and are suspended at such height above a Bunsen flame as to become warm to the hand in the course of half an hour, to be heated to 90° C. in a second half-hour, and finally, to become red hot at the point of impingement of the flame.

Portland cement may be considered as free from tendency to blow when test pieces treated in the manner described retain their hardness and coherence, and are not cracked or buckled.

The Roman cements tested were nearly all quick-setting, the initial set being perceptible in about two minutes. In general, Roman cements set the quicker the richer they are in clayey constituents, and the slower the higher is their content of lime. An excess of lime, if evenly distributed, appears to increase the setting time, although it may act in a contrary manner on the initial setting time. This may be explained by the fact that the heat evolved by the slaking of the lime sensibly aids the reactions involved in initial setting, while the presence of this same lime delays the ultimate hardening of the whole mass of the cement. Thus it happens that cements are met with which begin to set quickly and then remain soft for hours. Both from the not infrequent presence of free lime in Roman cement and from its common property of setting quickly, it is to be expected that the rise of temperature which it gives would be greater than that observed in the case of Portland cement. As much as 20° C. may represent this rise. Both Roman and Portland cements show a certain correspondence between the rise of temperature and the rate of setting, the amount of the former, when taken at successive periods of half a minute, falling at or near the time when initial set declares itself. The fallacy of supposing that an unsound cement necessarily gives a high rise of temperature is shown by the figures given by the author for six cements which were indisputably unsound, and yet gave no abnormal results when tested for the heat evolved during their setting. Similarly the fallacy that a cement giving a high rise of temperature is necessarily unsound is shown by the results obtained for Roman cements having as high a rise as 20°, and yet being of faultless quality.

The specific gravity of the Roman cements tested, varied between 2.81 and 3.13, this variation being doubtless due to the somewhat wide range of composition characteristic of this material. A high specific gravity due to comparative richness in lime may not coincide with a high tensile strength, because of the irregular distribution of the lime, making the cement latently unsound and diminishing its strength. It appears to be generally true that Roman cement has a higher strength when kept in air than when kept under water, the differences being in some cases very large, especially when there is reason to consider the cement overlined or containing lime irregularly distributed. Exposure of Roman cements to air causes them to absorb water and carbonic anhydride, whereby their specific gravity is decreased and they become slower setting, while their tensile strength is augmented. The last effect may well be attributed to the character of these cements, which, from the nature of their raw material, the small amount of care expended on their manufacture, and their comparative cheapness, are liable to contain tolerably coarse particles of lime, which are gradually slaked by exposure to air to the benefit of the cement. It may be remarked that an apparently low tensile strength may sometimes be obtained from a cement of good quality on account of the excessive quickness with which it sets making it difficult to gauge the briquettes before setting has begun.

The following rapid tests were used for Roman cement:—

(1.) *The Hot-water Test.* Balls of neat cement, after 24 hours' hardening in moist air, are placed in water, which is brought to a temperature of 50° C. in the course of half an hour, and are kept there for 3 hours.

(2.) *The Steam Test,* which is carried out in precisely the same way as for Portland cement and has been already described. Cement which stands this test is undoubtedly sound, but many cements of fair quality may fail under it, in which case, provided they stand the hot-water test, they may be accepted.—B. B.

Arsenic, A Rapid Process for the Estimation of. R. Engel and J. Bernard. *Comptes rend.* 1896, **122**, 390.

THE following method is intended to replace the delicate and somewhat lengthy process described by Gantier (*Bull. Soc. Chim.* **24**, 251), in which the ring of arsenic obtained by Marsh's test is weighed.

The arsenic solution, concentrated if necessary in alkaline solution to 20–40 c.c., is mixed with three times its volume of hydrochloric acid of 22° B_e, and then with a large excess of hypophosphorous acid (according to the quantity of arsenic, 4–10 c.c. of acid of 30° B_e). After standing 12 hours at the ordinary temperature, the arsenic is completely precipitated in the metallic state; the vessel is then warmed on the water-bath and boiling water added to facilitate the filtration. The vessel is repeatedly washed out with boiling water until the filtrate is no longer acid, no attempt being made to remove the arsenic adhering to its sides; the filter paper is then placed in the same flask and a decinormal solution of iodine added with constant shaking until the liquid remains coloured. The arsenic is now in solution in the state of arsenious acid, then 50 c.c. water and 10 c.c. of saturated sodium or potassium bicarbonate solution are added, and the titration finished, using starch as indicator. The process determines small quantities of arsenic alone or in presence of other metals (nickel, cobalt, manganese, aluminium, zinc), with an error of about $\frac{1}{10}$ mgrm.

—A. C. W.

Arsenic, The Determination of. A. Gantier. *Comptes rend.* 1896, **122**, 426.

THE method of Engel and Bernard (previous abstract) is not suitable for determining accurately quantities of less than 1 mgrm., which the author's method exactly estimates. The volatility of arsenic and antimony affords a means of separating these elements from other metals, in however small a quantity they may be present, and according to his method, these two metals may be then separated from one another and both estimated.—A. C. W.

Cobalt and Nickel, Separation of. Carnot. *Berg. u. Hüttenmänn. Zeit.* **54**, 370.

AFTER throwing down both metals with bromine and potash the liquid is boiled and the precipitated sesquioxides are washed, reduced by heating to redness in a current of hydrogen, re-washed, and weighed together. They are then redissolved in nitric acid and the solution divided. From the one part are precipitated by hydrogen peroxide and potash, the protoxide of nickel and the sesquioxide of cobalt, the latter being titrated with potassium iodide and sodium thiosulphate. The second portion is neutralised with potash and the precipitate redissolved with potassium cyanide. Bromine is added and the precipitated sesquioxide of nickel estimated by means of iodine, the cobalt remaining in solution as cyanide.

Another method of separation consists in adding molybdate to the ammoniacal solution, whereupon rose cobalt molybdate comes down, being almost insoluble in the cold liquid. On the other hand, the molybdate of ammonia and nickel is very soluble. This method is advisable where the quantity of cobalt is small.—C. S.

Pig Iron, Sulphur in; Drown's Method of Determining. G. Auchy. *J. Amer. Chem. Soc.* **18**, [4], 406–411.

THE addition of potassium hydroxide to the potassium permanganate solution used to oxidise the evolved gas, is recommended, since, by reason of the greater oxidising power of this mixture, the gas may be passed through the

solution at a more rapid rate without danger of loss. Moreover, the precipitated manganese oxide is easily washed out with water, instead of having to be dissolved in strong hydrogen chloride. The silica in the potassium hydroxide may be disregarded, being without effect on the subsequent precipitation of barium sulphate.

The addition of oxalic acid in connection with hydrogen chloride in preparing the clear solution of manganese facilitates the operation, without retarding—in fact, assisting—the precipitation of the barium sulphate, or causing contamination from barium oxalate.

It is advisable not to have any ammonium chloride present in strongly acid solutions, and ammonia, if used at all, should therefore be added to near neutralisation.—C. S.

Copper, Quantitative Estimation and Separation of. F. Mawrow and W. Muthmann. *Zeits. anorg. Chem.* 1896, **11**, 268.

FOR the separation of copper from zinc and cadmium the authors apply the well-known reaction of copper salts with hypophosphorous acid. Copper cannot be satisfactorily precipitated by this reagent from solutions containing chlorides, since cuprous chloride is first formed and is difficult of reduction; the presence of sulphates, acetates or nitrates, is permissible, provided there be not too much free nitric acid. Commercial hypophosphorous acid is employed, for its impurities are practically only calcium sulphate and free sulphuric acid. For the separation of copper from cadmium in qualitative testing, the solution containing the metals is mixed with an equal volume of the reagent and the mixture is boiled until the copper has separated in the form of dark-coloured flocks; after filtration the cadmium can be precipitated as sulphide completely free from copper sulphide. For quantitative precipitation, solutions containing hydrochloric acid are evaporated with sulphuric acid and then diluted, until the copper bears the proportion of 0.1 gram. to 100–200 c.c. of water; several c.c. of hypophosphorous acid solution are added and the liquid boiled until no more hydrogen escapes. The precipitate is collected on a weighed filter, washed with water, alcohol, and ether, dried at 100°, and weighed.—A. G. B.

Alumina in Phosphates, Determination of. H. Lasne. *Bull. Soc. Chim.* 1896, **118**–**128**, 146–157, 237–248.

IN the manufacture of superphosphates, the presence of sesquioxides is prejudicial, and a sample containing more than a certain amount of iron and aluminium oxides would be rejected. The analysis of the iron presents no difficulty; its estimation volumetrically in presence of phosphates can be carried out with exactitude. It is, however, otherwise with aluminium, and the estimation of this metal in presence of phosphates is a matter of some difficulty. The new method proposed by the author, which possesses several advantages, amongst others that of rapidity, is carried out as follows:—The solution of the phosphate freed from silica is poured into a solution of pure caustic soda containing sodium phosphate more than sufficient to combine with the whole of the lime. On boiling for about half an hour, the solution contains the whole of the aluminium. The aluminium phosphate, after precipitation with ammonia, is redissolved in dilute hydrochloric acid and finally precipitated with ammonium hyposulphite and boiled for half an hour, a few drops of a saturated solution of ammonium acetate being finally added to ensure complete precipitation. The precipitate, after heating before the blowpipe for 15 minutes, has the composition $\text{PO}_4\text{Al}_2\text{O}_3$. The author gives confirmatory evidence in support of his new method and a series of experimental data with respect to various other methods.

—T. A. L.

Fertilisers, Commercial: Phosphoric Acid in. Various Modifications of the Pemberton Method of Determination. F. P. Veitch. *J. Amer. Chem. Soc.* **18**, [4], 389–396.

THE conclusions drawn by the author, from his experience with modifications by Kilgore of the Pemberton process (*J. Amer. Chem. Soc.* **15**, 382), are that the addition of nitric acid to the molybdate solution gives results fairly concordant with gravimetric estimations, and that no advantage is gained by employing tartaric acid with the molybdate.

He prefers to use the official molybdate solution with 10 per cent. of nitric acid, filtering without pressure, and washing solely with water, as giving quicker results than the usual method.—C. S.

ORGANIC CHEMISTRY.—QUALITATIVE.

Rosin and Rosin Oil, Detection of, in Oils and Varnishes.

F. Ulzer. Mitt. k.k. Techn. Gewerbe-Museum (Vienna), 1896, 91, 92.

THE Storch-Liebermann reaction for the detection of rosin by means of the red coloration produced by the action of sulphuric acid on a solution of the rosin in acetic anhydride, has been modified by Morawski, who uses sulphuric acid of sp. gr. 1.53 instead of the concentrated acid, and has applied the test to the detection of rosin in the sizing of paper and in soaps, and has also stated that rosin and rosin oil may be detected in most fatty oils by shaking out with acetic anhydride and adding to the solution sulphuric acid of the density named above.

The author has found that boiled linseed oil, in whatever manner it may have been prepared, itself gives a reaction when its solution in acetic anhydride is treated with sulphuric acid, the colour produced being red-brown.

It is impracticable to shake out the boiled linseed oil with acetic anhydride, because it dissolves freely in that menstruum and also easily forms an emulsion therewith. An improvement in the process consists in shaking out the boiled linseed oil with absolute alcohol, allowing the mixture to stand for some hours, separating and evaporating the alcoholic solution, dissolving the residue in acetic anhydride and treating it with sulphuric acid. Even the pure boiled oil gives a red colour when thus treated, but large quantities of rosin oil or of rosin, can nevertheless be detected. With regard to the use of the reaction for varnishes, it is necessary first to ascertain what is the behaviour of the many resins used for varnish making. The author's experiments go to show that only a few resins give the reaction, and especially that all the copals tested (Manilla, West Indian, Cowrie, Angola, Zanzibar and East Indian) give only a more or less intense brown colour which is not to be confounded with the reaction of common rosin. Amber behaves similarly to copal; and sandarac, dammar, mastic, and shellac also do not give the rosin reaction, which, however, is afforded by elemi.—B. B.

Mineral Oils, Fatty Oils in; Detection of. G. Halphen. Ann. Chim. Anal. Appliq. 1896, 1, 29.

ROVÈRE's reaction, consisting in the addition to the oil of a fuchsin solution previously decolorised by the regulated addition of an alkali, depends on the presence of free fatty acid in the oil, and is accordingly valueless, because mineral oils may contain sufficient organic acid to cause the formation of a red colour. Moreover, oils containing soap will not give a reaction. A soap present in a mineral oil may be readily detected by use of a solution of Congo red, previously faintly acidified so that its colour is violet. The alkalinity of the soap causes a change of colour to red.

—B. B.

Lubricating Oil, Soap in; Detection of. F. Jean. Ann. Chim. Anal. Appliq. 1896, 1, 31.

SCHWEITZER's reagent, which is a saturated solution of metaphosphoric acid in absolute alcohol, may be used for the detection of small quantities of soap in lubricating oils by adding it to an ethereal solution of the oil, whereby a precipitate is produced. The precipitate may be treated with platinum chloride, and from its behaviour with that reagent some conclusion as to whether it is a potassium or sodium soap, or the soap of some heavy metal may be drawn.—B. B.

Boric Acid, Apparatus for the Detection of. W. M. Doherty, Government Laboratory, New South Wales. Proc. Chem. Soc. 1895, [161], 101.

THE milk, wine, or other substance is made slightly alkaline with sodium carbonate, and after drying, it is thoroughly charred—not burned to an ash. The charred mass is ex-

tracted with boiling water, and the solution obtained made acid with hydrochloric acid, and evaporated gently over the water-bath in a small porcelain boat, which is placed in an apparatus of the following description.

A piece of glass tubing, about 9 in. long and $\frac{1}{2}$ in. in diameter, is turned over at right angles at one end and drawn to a fine aperture. A second piece of tubing about $2\frac{1}{2}$ in. long, and $\frac{1}{2}$ in. in bore is provided with a hole in the side, and placed over the aperture and arranged so as to form a glass Bunsen burner.

The porcelain boat or other vessel containing the properly prepared substance, supposed to contain the boric acid, is placed in the larger tube, which is attached at the wide end to the gas supply, the whole being supported by a clamp. The gas is regulated so as to produce a clear flame about $\frac{1}{2}$ in. long, and free from luminosity at the extremity of the upright tube. The vicinity of the porcelain boat is heated by an ordinary Bunsen burner, and if boric acid be present, even in the most minute quantity, the small flame will show it distinctly. It will be found desirable to apply the heat gently, increasing it slowly, and carefully observing the flame in the meantime.

Formalin, Further Notes on the Detection of. H. D. Richmond and L. K. Boseley. Analyst. 21, 92.

THE authors think that Rideal (this Journal, 1895, 14, 766) in concluding that milk contains a non-volatile aldehydic compound, because all samples give a pink colour with Schiff's reagent, has overlooked the fact that aldehydes do not give a pink colour with Schiff's reagent but a reddish-violet one; alkalis either free or combined with a weak acid give a pink colour. Schiff's reagent, if prepared according to Caro's directions with rosaniline, sodium sulphite, and hydrochloric acid, always contains an excess of the latter, and this excess whilst it has no effect on the colour given by aldehydes, prevents the formation of the pink colour.

With regard to the delicacy of the different reactions for detecting formalin, it was found that the reduction of silver nitrate is, though very delicate, of so general a character as to be misleading, even when following Tollen's directions (Ber. 15, 1635).

Schiff's test is very delicate, but must be performed in a slightly acid solution. It was found that milk sugar, even after boiling with dilute sulphuric acid gave no colour, and the authors consider it quite safe to test the whey produced by adding dilute sulphuric acid to milk, thus avoiding the troublesome distillation.

The authors found that the delicacy of Hehner's reaction (Analyst. 20, 155; this Journal, 1895, 14, 772) may be much increased by diluting the milk with an equal bulk of water, and adding sulphuric acid of 90–94 per cent. In the absence of formaldehyde, a slight greenish tinge is apparent at the junction of the two liquids, whilst a violet ring is formed if formaldehyde be present.

Trillat's reaction with dimethylamine (this Journal, 1893, 789) is less delicate, but does not require any distillation. The blue colour is not very stable.

Pföchl's test (Ber. 21, 2117) is of no use with very small amounts of formaldehyde.

The authors' test with diphenylamine (this Journal, 1895, 772) and Trillat's aniline test (this Journal, 1893, 789) are both less delicate than the foregoing. The authors correct their statement (this Journal, 1895, 772) that the precipitate in their diphenylamine test is coloured green if the acid used contains nitrates. The green coloration appears on continued boiling, even when the acid used contains no nitrates.

The authors think that Hehner's method is the best for the detection of formalin in milk, with Schiff's test (in the whey produced by sulphuric acid) and Trillat's dimethylamine test to confirm.—A. S.

Formalin, the Detection of. O. Hehner. Analyst. 21, 94.

SCHIFF's test for formalin acts very slowly when only very small quantities of formaldehyde are present. The proper amount of formaldehyde present in milk for preserving purposes is 1 part to 60,000 parts of milk,

and Schiff's reagent will only indicate such a trace after some hours standing. The author states that Schiff's reagent may give a red coloration, even with pure distilled water in stoppered cylinders, if the reagent be not added in sufficient excess. The best way of performing Schiff's test is to add about 5 drops of the reagent to the distillate from 100 c.c. of milk (amounting to about 25 c.c.), allow to stand till the next morning, and then add a few drops of sulphurous acid solution. Any colour which may be due to oxidation will disappear after a short time, while that due to the presence of an aldehyde remains. The colour produced by oxidation resembles that of rosaniline, whilst that of the aldehyde compound is violet, and with small traces, only a comparison of the relative colours would allow of a safe conclusion being drawn. The author concludes from his experiments that Schiff's test is a dangerous one, and should only be used as a confirmation.

The author gives the results of some experiments, made in January, as to the rate at which formalin disappears from milk on keeping. The formaldehyde, in a sample which contained 1 part of formaldehyde in 100,000 of milk, had disappeared after one week; from a sample which contained 1 part of formaldehyde in 50,000 of milk, the formaldehyde had disappeared after two weeks; whilst in a sample containing 1 in 25,000, only the faintest trace of formaldehyde could be detected after three weeks.

With the author's test (this Journal, 1895, 772), 1 part of formaldehyde can readily be detected in 200,000 of milk. The author does not agree with Richmond and Boscley (this Journal, 1895, 772) that formaldehyde will give this test with peptone and sulphuric acid, and he states that although egg-albumin gives the reaction, it is probably due to some impurity.

Casein, precipitated from milk, re-dissolved in alkali, and again precipitated and dissolved, gives the reaction most strongly; milk whey also gives it.

The reaction can be used for detecting formaldehyde in wine or vinegar, by adding a drop of milk to the sample and pouring the mixture on to the surface of strong sulphuric acid. A blue ring appears at the junction of the two liquids when formalin is present. Butter can also be tested, by using the aqueous liquor resulting when it is melted.

The following equally sensitive and characteristic test is given:—

One drop of a dilute aqueous solution of phenol is added to the distillate from a sample of milk, &c., and the mixture is poured on to strong sulphuric acid. If formaldehyde be present, a bright crimson colour appears in the zone of contact. This test acts readily with 1 part of formaldehyde in 200,000 of water. If there be more than 1 part in 100,000, a white milky zone is seen above the red ring, whilst in stronger solutions, a copious white or slightly pink curdy precipitate is obtained. The precipitate obtained by phenol, sulphuric acid, and formaldehyde is so insoluble that it might be utilised for the determination of the strength of dilute formalin solutions.

The milk-, sulphuric, and the phenol-sulphuric tests are more delicate than the silver nitrate test.—A. S.

Petroleum, Sulphur in. C. Engler. Chem. Zeit. 1896, 20, 197—199.

THE development of the Ohio oilfield has brought into the market considerable quantities of burning oil from this district, but objection has been raised against its use on the score of the unusually high percentage of sulphur in the crude Lima oil. In order to see how far this is justified, the author has devised a testing apparatus to determine the amount of sulphur actually present in refined petroleum. In place of potassium permanganate, as proposed by Hensler (this Journal, 1895, 828), he prefers to absorb the products of the combustion of the oil by a solution of bromine in potassium hydroxide or potassium carbonate. A shallow oil receiver A, containing about 100 c.c., is fitted with wick and wick duct *a*, this shape being adopted to keep the level of the oil from sinking too rapidly, and to thereby ensure regularity of combustion. The height of the flame from the base of the lamp is 9 centimetres, and the cylinder B is fused on to a glass tube *b*, which extends

almost to the bottom of the absorption vessel C, filled with small glass balls or pieces of glass rod, and connected

at the upper end with an aspirator, the lower extremity terminating in a tube fitted with a tap. The cylinder B fits on to a ring of cork on the neck of the receiver, air being admitted to the burner through the tubes in the metal capsule *d*, which can be connected with a supply of pure air if the atmosphere of the laboratory contain sulphur. On the other hand, if the air in the testing room be not contaminated, the cork and capsule may be discarded.

The absorbent liquid is prepared by adding to a 5 per cent. solution of potash enough bromine to produce a pale yellow coloration, which is then removed by exposure to air. This solution will absorb and oxidise sulphur dioxide completely, can be readily prepared free from sulphur, and entails no risk of the earthenware connections becoming attacked by the vapour of bromine. Besides, until the gases reach the absorption tube they come in contact with glass exclusively.

The test is performed as follows:—

The absorption tube being filled with 20 c.c. of solution, the lamp, containing a known weight of oil is lighted, and a good draught induced by the aspirator, but not so strong as to make the flame smoke or draw the solution out of the absorption tube. After burning about 5 hours, 10 to 12 grms. of oil will have been consumed, the exact weight being ascertained by difference, and the lamp may then be extinguished. The solution is drawn off, and the vessel rinsed out two or three times with 20 c.c. of water, air being drawn through each time. The sulphuric acid is then determined as barium sulphate in the usual manner.

The method tested on oils containing a known percentage of sulphur, added by means of ethyl sulphide, proved correct to within narrow limits in the third decimal place.

Of a number of commercial oils examined, water-white Ohio oil was found to contain 0.0244 per cent.; Baku oils, 0.0262—0.0267; Pennsylvania oils, 0.0211 to 0.0362; Lima oils, 0.0432 to 0.0509; Austro-Galician oils, 0.0406 to 0.0615; and Alsatian oils, 0.0661 to 0.0684 per cent. of sulphur. The largest amount (0.2098 per cent.) was discovered in a "safety oil," but this is considered as an exceptional case.

These results show that in this respect, Lima oil, when properly refined, comes midway between Pennsylvanian and Alsatian oils, and no reason exists for the objection urged against it on this score. Furthermore, it is evident that the amount of sulphur compounds introduced into the air by the combustion of petroleum oils compares favourably with that resulting from coal gas. For example, a 14-line burner consuming 50 grms. of oil per hour gives off only 0.01 to 0.02 (or at most 0.035) grm. of sulphur

(about as much as an ordinary sulphur match), which is equivalent to about 0.1225 grm. of sulphur per 100 candles per hour, whereas English gas containing the limit of sulphur allowed by law produces on the same basis 0.513 grm., and Karlsruhe gas (0.333 grm. of sulphur per cubic metre) 0.3 grm. of sulphur. Consequently any legislation directed against petroleum on this account would also have to be applied to gas.—C. S.

Petroleum, Estimating Sulphur in Burning Oil. R. Kissling. Chem. Zeit. 20, 199. (See preceding abstract.)

The apparatus is a modification of that of Heusler. It consists of a glass cylinder with the top drawn off, and bent through rather more than 90°; 26 ins. to the top of the bend. The diameter of the cylinder is 2½ ins. The absorbent liquid consists of a 5-per cent. solution of potassium permanganate, 15 c.c. of which are placed in a U-tube filled with glass balls, and 5 c.c. in a vessel similar to those employed in the Will-Varentrapp method of estimating nitrogen, a second vessel of the same kind being connected for catching any of the solution drawn out of the other by the aspirator. The air current, which should be as free from sulphur as possible, is drawn through the apparatus at the rate of some 300 c.c. per minute. In the course of the operation the solution in the U-tube is decolorised, but that in the other two vessels retains its red colour. Finally, the solution and washings are mixed with hydrochloric acid, concentrated to drive off chlorine and the excess of acid, and after filtration, the sulphuric acid therein is determined by means of barium chloride.

The results of the application of the test to 12 varieties of burning oil (all, except a Pennsylvania "Krönen" oil, being from German refineries) show that Lima oil (0.0444 to 0.0453 per cent.) contains little more sulphur than some Galician petroleum (0.0396 per cent.) and less than Alsatian oil (0.0588 to 0.0593 per cent.). Pennsylvania oils contained 0.0269 to 0.0286; "Kaiser" oil 0.0092 to 0.0109; "Safety" oil (85° Abel) 0.0188 to 0.0198; Russian oil 0.0298, and "Krönen" oil 0.0193 per cent. of sulphur. Any prohibition directed against Lima oil would therefore have to include Alsatian petroleum.

Further experiments confirmed the somewhat surprising fact that the percentage of sulphur is reduced by refining with sulphuric acid, the "Kaiser" oil, which at first contained 0.03 per cent., containing after treatment with this acid only 0.01 per cent. of sulphur.—C. S.

Caffeine, Action of Wagner's Reagent. A New Method of Estimation. M. Gomberg. J. Amer. Chem. Soc. 18, [4], 331—342.

The author proposes to utilise the reaction for the quantitative estimation of the alkaloid, by employing as precipitant a solution of a known quantity of iodine in potassium iodide and titrating the unconsumed iodine by deci-normal sodium thiosulphate. In his experiments with varying quantities of the reagent he finds the most accurate results (averaging about 99.5 per cent.) are obtained by the use of double the theoretical quantity, in presence of about 2 per cent. of acid (hydrochloric acid being probably better than sulphuric acid). In applying the method to drugs, the extract is treated with lead acetate and filtered, the lead being then removed by hydrogen sulphide. The liquid is subdivided, one part being acidified with a mineral acid before adding the Wagner reagent. This allows the presence of any other materials that may form precipitates with the reagent to be detected in the acetic solution, the difference in the quantities of iodine absorbed in the two solutions representing the amount combined with the caffeine.—C. S.

Oils, Determination of the Heat of Bromination in. H. W. Wiley. J. Amer. Chem. Soc. 18, [4], 378—385.

The method proposed is a modification of that of Hehner and Mitchell (Analyst. 20, 146), and, briefly, consists in dissolving the fat or oil under examination, in chloroform or carbon tetrachloride (the latter by preference) at the rate of 10 grms. per 50 c.c. (final measurement), and adding the

bromine, also in a state of (25 per cent.) solution, in the same solvents.

The apparatus is composed of a tube, for the reagents and thermometer, 40 cm. long and 1½ cm. internal diameter, inserted in the cylinder of a drying-jar through an air-tight stopper. The air in the jar being exhausted through the lateral tubulure, 5 c.c. of the solution of fat are placed in the bottom of the tube, by the aid of a pipette, without touching the sides, and the thermometer is placed in position. The bromine solution is contained in an Erlenmeyer flask with a side tubulure fitted with a rubber bulb, and is forced into a pipette—inserted through a rubber stopper in the mouth of the flask—by compressing the bulb. 5 c.c. of the solution are then allowed to flow from the pipette into the solution of fat, and the rise in temperature, which will attain its maximum in about a minute, is carefully read off by the aid of a hand-glass.

The operation can be performed in two minutes, and the apparatus will be cool enough in half an hour for another determination.

The advantages claimed are readier manipulation of the bromine and the saving of time lost in weighing out the fat separately for each test. The temperature of the room should be as constant as possible.

The constant factor of relation between the heat of bromination and the iodine absorption number established by Hehner and Mitchell will have to be recalculated for this method, owing to the altered conditions. The liquids should not be agitated, or heat will be lost and the results come out too low.

Carbon tetrachloride is preferable to chloroform, on account of the rise in temperature occurring when the latter is mixed with bromine, this amounting to about 1.3° C., and being due to the reaction set up between them.—C. S.

Pyroligneous Products, On the Determination of the Acidity of. Note by M. Scheurer-Kestner. Comptes rend. 1896, 10, 619.

CRUDE pyroligneous acid obtained by the destructive distillation of hard woods in closed vessels, although consisting chiefly of acetic acid, yet includes many substances of which as yet the composition is imperfectly understood. It contains esters having acetyl as their base, as well as phenols, in notable proportion, and these interfere, though in opposite directions, with the titration by an alkaline solution, so that the error introduced by direct titration is less apparent than if only one disturbing factor operated.

Methyl acetate, which occurs in the crude acid in considerable proportion, resists alkaline titration; nevertheless the result is always too high, owing to the action of the phenols present. The proportion of methyl acetate may be determined by titrating the crude acid with caustic soda solution, using phenolphthalein as indicator; then boiling the same acid with an excess of the soda solution for some hours, and again titrating. The difference found between the two tests gives the proportion of methyl acetate, which is usually equivalent to 15 to 17 per cent. of acetic acid.

Some crude (but limpid) pyroligneous acid was kept in a closed flask for 30 days. The bottom of the flask was then covered by an oily, phenolic layer. The acid, titrated before and after the subsidence, showed a difference of 8 per cent. due to the phenol separated, of which nevertheless, much was still retained in solution by the alcohols and esters present in the liquid.

To obviate these sources of error, the author distils 20 grms. of the crude acid with 50 grms. of phosphoric acid solution of 15° B. When only a small quantity of liquid remains in the retort, 20 c.c. of water are added, and the distillation is continued. After three such distillations, the process is usually complete, and on combining the distillates and titrating, an accurate result is attained. An experiment thus conducted upon a sample taken from a very large quantity of the crude acid, gave a difference of 10.5 per cent. in titration, as compared with the direct test, the latter being in excess.

The phosphoric acid process described, is also available with like precautions, in estimating the acetic acid contained in crude acetates of iron and aluminium.—E. S.

Anthracene Testing, Improved Method of. H. Bassett.
Chem. News, **73**, 178-179.

THE anthracene is subjected to oxidation in the usual manner, using 15 grms. of pure chromic acid. Next morning the product is diluted with 400 c.c. of water, allowed to stand for three hours, filtered, washed with cold water only, and dried on the filter in the water-oven. The quinone is then transferred to a flask of the usual size, with the aid of a funnel, with a short and wide neck, and a glass rod, using a small wash bottle containing 45 c.c. of glacial acetic acid to rinse the filter-paper, rod, and funnel, 2.5 c.c. of chromic acid solution, and 10 c.c. of ordinary pure nitric acid of sp. gr. 1.42 are then added, after which the mixture is boiled for an hour with the usual condensing tube. Next morning, the product is diluted with 400 c.c. of water, allowed to stand for three hours, filtered, washed first with water, then with boiling 1 per cent. alkali, and finally with hot water. The quinone is then washed into a flat dish, dried at 100°, and heated for ten minutes on a water-bath with 10 times its weight of pure concentrated sulphuric acid. It is then left all night to absorb moisture, in a tray of water covered by a glass plate, diluted, filtered, washed with water, boiling alkali, and hot water, and finally dried and weighed as in the ordinary way.

The results obtained with a fairly representative number of commercial and other samples of anthracene are given, showing the percentage loss on the value by the ordinary test. The author suggests that a comparison of the results obtained by the two methods may lead to a reliable conclusion as to the quality of the anthracene under examination. With the ordinary method, the colour of the final product, especially in the case of the so-called "R" qualities, is more or less brownish, but with the nitric acid process, all samples, good or bad, are said to give a clean yellow quinone, which gives rise to less carbonisation on sublimation. The final product is quite free from nitro compounds.—D. B.

Benzidine and Tolidine, Valuation of. W. Vaubel. Zeits. anal. Chem. 1896, **35**, 163.

THE determination of these bases in the commercial article by nitrite is not adapted to the purposes of the Congo-red manufacture, since this reagent also determines the other bases present which will not yield a cotton dye. A volumetric method founded on the precipitation of the sulphate from a hydrochloric acid solution of the base, only gives approximate results because of the greater solubility of the sulphate in hydrochloric acid than in water.—A. C. W.

Naphthols and Naphthylamine, Behaviour towards Nascent Bromine. W. Vaubel. Zeits. anal. Chem. 1896, **35**, 164.

BROMINE, liberated on the addition of a solution of potassium bromide and bromate to an acetic acid solution of the following substances in the presence of strong hydrochloric acid, is absorbed (one atom), and the end-point of the reaction is well marked:— α -acetylnaphthylamine, β -naphthol, the ethers of α - and β -naphthol. Monobromo- β -naphthol methyl ether separates as white shining needles, melting at 85°, the bromomethyl ether in plates melting at 54°.—A. C. W.

Gutta-Percha, Analysis of. J. Montpellier. Ann. Chim. Anal. Appl. 1896, **1**, 1.

DETERMINATIONS are made of moisture; gutta-percha proper; the resins, fluavil and alban; inorganic matters (ash); and extraneous matters, if any should be present.

The moisture is estimated by heating for 6-7 hours at 100° in an atmosphere of carbon dioxide or nitrogen.

The gutta-percha is directly, and the resins are indirectly, determined by extracting with alcohol 0.5-1 gm. of the finely divided sample, and drying the residue of gutta-percha in a current of carbon dioxide at 100°.

An approximate separation of the resins may be effected by concentrating the alcoholic extract, when the alban crystallises out. This is thereupon collected, dried in carbon dioxide, and weighed, the fluavil being estimated by difference.

The ash should not exceed in amount 0.5 per cent. Foreign matters may usually be determined by taking not more than 1 gm. of the sample and extracting with chloroform, which dissolves the gutta-percha and resins, and leaves most other matters undissolved.—E. B.

Tannin Estimation, Remarks on the Vienna Method of.

J. Schneider. Casopis českého lékařnictva, 1896, **15**, 4.

INSTEAD of sucking the tannin liquor through the hide-powder filter, the author forces it through by pouring it down a long funnel attached to the wider bent tube shown in the figure.

The tube containing the hide powder (6 grms.) is 13 cm. long and 2 cm. in diameter, and the powder is prevented from passing into the entrance and delivery tubes by plugs of brass wire gauze or cotton wool. The influx tube is

8 mm. in diameter and 150 cm. long to the funnel. At the beginning, the tannin liquor must be added very slowly, so that at no time may the liquid stand in the influx tube at more than 5-10 mm. higher than in the hide-powder tube. When the powder has been wetted by the liquor the influx tube may be completely filled. The first portion of 5 c.c. of the filtrate is rejected, after which the apparatus requires no attention.—A. G. B.

Butter, Method for Determining the Purity of, by Means of the Density. R. Brullé. Comptes rend. 1896, **122**, 325.

EXPERIENCE proves that by taking care to eliminate the water which the fused fat almost always retains in variable proportion, as well as the colouring matter and the casein, so as to render the fats comparable with each other, the density, determined at 100° by a very delicate hydrometer, may be made to furnish very exact indications of the proportion of foreign fat fraudulently added to butter.—L. A.

Butter-Fat and its Substitutes, Examination of. H. Bremer. Forschungs-, Lebensmitt. Hyg. foren.-Chem. Pharmakogn. 1895, **2**, 424.

THE author recommends the following method, which combines the Meissl with the Köttstorfer method and by which the absorption of carbon dioxide is avoided, and likewise the action of the excess of alkali on the alcohol and the fat. Five grms. of the clear melted fat (free from moisture) are heated in a 300 c.c. Schott flask with 10 c.c. of alcoholic potash (containing 1.25-1.35 gm. KOH); the flask is fitted with a long condensing tube provided at its upper end with a Bunsen valve. When the reaction is complete, the flask is allowed to cool, the valve is opened, the tube removed, and the product titrated with alcoholic sulphuric acid. The saponification number can then be calculated. About 10 drops of alcoholic potash are added to the contents of the flask, which is then heated to expel the alcohol; the dry soap is dissolved in 100 c.c. of water (free from CO₂), a few pieces of pumice and 40 c.c. of dilute sulphuric acid (1:10) added and the whole distilled until 100 c.c. have come over for the determination of the volatile fatty acids.—A. K. M.

Gelatin in Meat Extracts and Commercial Peptones, Estimation of. A. Stutzer. *Zeits. anal. Chem.* **34**, 568.

THE extract is dissolved in a sufficiency of hot water in a dish of tin foil, and the solution mixed with enough calcined sand to absorb the liquid. The mixture is then ground, the dish cut up into strips, and the whole placed in a beaker, where it is extracted four times in succession, each time with 100 c.c. of absolute alcohol, the supernatant alcohol being passed through an asbestos filter in such a manner as to bring as little as possible of the solids on to the filter. After cooling in ice, further extraction is effected by means of a mixture of 100 grms. of alcohol, 300 grms. of ice, and 600 grms. of cold distilled water, at a temperature not exceeding 5° C., several times repeated until the liquid is no longer coloured. A separate filter is employed for each operation, and these are afterwards boiled repeatedly in water, the residues being united and concentrated, and the gelatin estimated therein.—C. S.

Cheese, Extraction of Fat for Examination. O. Hensold. *Milch. Zeit.* **24**, 729.

THREE hundred grms. of cheese are crushed in a mortar and shaken up in a wide necked flask with 700 c.c. of potash solution (containing 50 grms. of caustic alkali per litre) at 20° C. In a few minutes the cheese will be dissolved, and the fat left floating on the surface in small lumps, which can be induced to coalesce by moving the flask backwards and forwards. Cold water is poured in until the flask is full, and the butter can be collected in a spoon, washed in cold water—to remove the traces of potash and help the fat to set—pressed to remove the water as much as possible, remelted, and filtered. This method leaves the milk fat unchanged, and the author has also found that it likewise remains unaltered during the preparation and ripening of the cheese.—C. S.

Quinine, Note on the Titration of. A. H. Allen. *Analyst*, **21**, 85.

IN estimating alkaloids by titration with standard acid, phenolphthalein is useless as an indicator, whilst litmus will only answer in some cases. With methyl-orange, in the majority of cases, a determination of tolerable accuracy and a fairly sharp end reaction are obtainable. Cochineal, brazil-wood, and logwood may also be used sometimes as indicators.

The ordinary quinine sulphate of commerce—

is strongly alkaline to methyl-orange, although practically neutral to cochineal, brazil-wood, and logwood. In titrating quinine, therefore, with cochineal, brazil-wood, or logwood, the point of neutrality is reached when all the quinine has been converted into $(C_{20}H_{21}N_2O_2)_2H_2SO_4$, whilst, with methyl-orange as indicator, the end-reaction is not obtained until the quinine is converted into $(C_{20}H_{21}N_2O_2)_2H_2SO_4$. The results are similar if nitric or hydrochloric acid be substituted for sulphuric acid.

The sparingly-soluble sulphate $(C_{20}H_{21}N_2O_2)_2H_2SO_4$ is alkaline to litmus, and hence this indicator cannot be conveniently used for the titration of quinine, although the end-reaction is well marked.

The author states that Seaton and Richmond's method for the determination of quinine in medicine (*Analyst*, **15**, 43) is of little value for practical purposes. It is useless in presence of citric and other organic acids, and the colouring matter present in quinine wine prevents the end-reaction being accurately observed.

Experiments made on the titration of cinchonine and cinchonidine with various indicators seem to render it doubtful if the correct constitution of these bases, or at least the composition of the commercial article, is known.

—A. S.

Cinchona Extract, Examination of. I. Hulsebosch. *Ber. Pharm. Ges.* **1895**, **5**, 286.

Estimation of Alkaloid.—1 grm. of extract is diluted with 5 c.c. of water and 5 drops of normal hydrochloric acid and transferred with 10 c.c. of water to an extractor. The extraction is continued for one hour with ether, in order

to remove all matters soluble in ether from the extract solution. A small tared flask is now adjusted, and 2 c.c. of normal caustic soda solution diluted with 3 c.c. of water are added to the contents of the extractor, and extraction continued for two hours with fresh ether. Finally, the ethereal solution is evaporated, the residue of alkaloid dried at 100° C. and weighed.

Estimation of Cincho Tannates.—10 grms. of the extract are diluted with 10 c.c. of sodium acetate solution (20 per cent.) in a weighed glass dish with vertical walls, and heated on the water-bath until the precipitate coagulates and adheres to the side of the dish. The liquid is then poured off, the cincho-tannate precipitate washed once with a little water, the remaining liquid sucked up by means of blotting paper, after which the dish with contents is dried at 100° C. The residue should weigh at least 1.2 grms. (12 per cent.), and, when finely powdered, should be pale flesh coloured.—H. T. P.

XXIV.—SCIENTIFIC & TECHNICAL NOTES.

Cereal Celluloses, The Constitution of the. C. F. Cross, E. J. Bevan, and Claud Smith. *Proc. Chem. Soc.* **1896**, [161], 95.

THE general bearings of the subject, of which this is a special part, have been dealt with in previous communications (*Trans.* **65**, 472; **67**, 433; *Ber.*, **1893**, 2520; **1894**, 1061; **1895**, 1940 and 2604; *J. Amer. Chem. Soc.*, **1896**, 8).

It is now shown that the cereal celluloses may be resolved by acids into soluble derivatives of their furfuroid constituents, leaving a residue of a normal cellulose, and a process has been devised which sharply effects this separation.

Two methods of hydrolysis have been studied: (1) treatment with acids of the series, $H_2SO_4 \cdot 2H_2O - H_2SO_4 \cdot 3H_2O$, in the cold, dilution and filtration from reprecipitated cellulose, the furfuroid remaining in solution; (2) treatment with dilute sulphuric acid, 1 to 2 per cent. strength, at 1 to 9 atmos. steam pressure. The best results are obtained on short heating (15 mins.) at 3 atmos. The furfuroid is then obtained quantitatively.

It is concluded that the furfuroid in question is a pentose, monoformal—

Such a compound, having the empirical formula of a normal cellulose, could arise within a cellulose complex by transformation of the terminal, CH_2OH , of a hexose molecule, i.e., an oxidation by internal rearrangement. The formaldehyde residue thus produced is not split off, but remains united by oxygen with the pentose residue which is simultaneously produced.

Fire-Damp, Composition of. Th. Schlæsing, jun. *Comptes rend.* **1896**, **122**, 398.

IT is necessary to know whether other combustible gases than methane are present in fire-damp, since in mines the determination of fire-damp is made by means of the limit of inflammability. Samples of gas were obtained from the principal types of French mines; the analyses of all except three show that practically the only combustible constituent is methane. The other three probably contained another gas; the results obtained would correspond to 2–4 per cent. of ethane.

Some of the samples contained a high percentage of nitrogen; this was shown to have an atmospheric and not a vegetable origin by a determination of the argon it contained.—A. C. W.

Benzene and Naphthalene Hydroxy-Carboxylic Acids, Decomposition of. P. Cazeneuve. *Bull. Soc. Chim.* **1896**, 72–82.

THE author, in a previous paper, pointed out that certain phenol carboxylic acids, when heated in presence of aromatic amines, give off carbonic acid at much lower temperatures, and more completely, than when heated with

water. For instance, gallic acid, when heated with aniline, gives pyrogallol and carbonic acid at 115°C ., whilst in presence of water the decomposition only occurs at about 200°C . An investigation of several analogous compounds has led to the formulation of certain rules regarding their decomposition under the conditions mentioned. (1.) The instability of the carboxyl group attached to the benzene nucleus increases with the number of hydroxyl groups present in the molecule. (2.) The same gradation in instability is observable in phenol carboxylic acids containing halogen or other substituting groups in the nucleus. (3.) Ortho-phenol carboxylic acids lose carbonic acid more readily than the para compounds, and these latter are more easily decomposed than the meta compounds, which possess a very considerable stability. Thus, for instance, guaiacol carboxylic acid is unaltered by heating with aniline to 240°C .—T. A. L.

Nickel and Cobalt Borides. H. Moissan. *Comptes rend.* 1896, 122, 424.

THESE borides, NiB and CoB , are easily obtained crystalline by heating the elements together in a current of dry hydrogen at a temperature above $1,200^{\circ}$. In properties they are quite similar to the boride of iron previously described.—A. C. W.

New Books.

A THEORETICAL AND PRACTICAL TREATISE ON THE MANUFACTURE OF SULPHURIC ACID AND ALKALI, WITH THE COLLATERAL BRANCHES. By GEORGE LUNGE, Ph.D., Professor of Technical Chemistry at the Fed. Polytechnic School, Zürich. Second Edition, revised and enlarged. Vol. III. Gurney and Jackson, 1, Paternoster Row, London. 1896. Price 2*l.* 2*s.*

The first edition of this volume filled 422 pages; the present second edition fills no less than 840 pages, which are illustrated with 248 engravings. Even a brief comparison of the two editions will prove the truth of the author's statement, that the present is not merely a "new edition" but practically "a new book." The Chapters on the ammonia-soda industry, on the more recent soda process, on the Deacon process, and the other chlorine processes, have had to be entirely re-written. Considerable space is also now occupied by electrolytic methods. The work comprises 30 Chapters, Statistics covering 12 pages, Addenda to Vols. I, II, and III, filling some 28 pages, and an Alphabetical Index. The treatment of the subject will be apparent from the following synopsis of the Contents:—

FIRST BOOK.—THE AMMONIA-SODA PROCESS. I. Historical and General. II. The Ammoniacal Solution of Salt. III. Production of Carbonic Acid. IV. Precipitation of Sodium Carbonate by the Carbonating Process. V. Filtering, Drying, and Calcining the Bicarbonate. VI. Recovery of the Ammonia. VII. Analyses, Costs, Statistics. VIII. Other forms of the Ammonia-Soda Process. IX. Manufacture of Commercial Bicarbonate by the Ammonia-Soda Process. SECOND BOOK.—VARIOUS PROCESSES OF THE ALKALI MANUFACTURE. X. Manufacture of Soda from Cryolite. XI. Manufacture of Soda directly from Sodium Chloride. XII. Manufacture of Soda from Sodium Sulphates without previous reduction to Sulphide. XIII. Manufacture of Soda from Sodium Sulphate after reducing it to Sulphide. XIV. Manufacture of Soda from Nitrate of Soda and Felspar. THIRD BOOK.—THE CHLORINE INDUSTRY. XV. General and Historical. XVI. Manufacture of Chlorine by Means of Manganese Ore. XVII. Utilisation of Still Liquor. XVIII. The Deacon Process. XIX. Properties and Behaviour of the Hypochlorites and of Bleaching Powder. XX. Manufacture of Bleaching Powder. XXI. Bleach Liquors. XXII. The Chlorates. XXIII. Other Processes for the Manufacture of Chlorine. FOURTH BOOK.—PREPARATION OF ALKALIS, CHLORINE, AND CHLORATES BY ELECTROLYSIS. XXIV. History, Theories, General Notes. XXV. to XXVII. Special Processes for the Electrolytic Production of Soda and Chlorine. XXVIII. Chlorine from Hydrochloric Acid, Bleach Liquor. XXIX. Chlorates. XXX. Special Forms of Electrodes and Diaphragms. STATISTICS. ADDENDA TO VOLS. I, II, AND III.

DIE DERIVATE DES NAPHTHALINS, WELCHE FÜR DIE TECHNIK INTERESSE BESITZEN. Uebersichtlich zusammengestellt von ERNST TÄUBER und RAGNAR NORMAN. Hermann Heyfelder, R. Gaertner's Verlagsbuchhandlung, Schöneberger-Str. 26, Berlin, S.W. H. Grevel and Co., 33, King Street, Covent Garden, London. 1896. Price M. 18 or 18*s.*

LARGE 8vo. volume, bound in cloth, and containing Preface, Introduction, Table of Contents, and 219 pages of subject-matter.

The work, as a whole, may be designated a *Vade mecum* to those derivatives of naphthalene which possess technical interest. The arrangement is mainly tabular, so that no alphabetical index is necessary. However, alphabetical registers are given of various subsidiary matters, and a valuable one of the Literature of the subject, with Authors', Patentes', or Firms' names, and references to the original papers or publications. Each Chapter describing a set of derivatives, is headed by a table in which the derivatives are placed and classified according to isomeric order.

The following are the derivatives described:—

Amidonaphthalene sulphonic acids, including Amidonaphthalene carbonic acids and Amidonaphthalene carbo-sulphonic acids.

Hydroxynaphthalene sulphonic acids, including Hydroxynaphthalene carbonic acids and Hydroxynaphthalene carbo-sulphonic acids.

Diamidonaphthalenes, including Triamidonaphthalenes. Diamidonaphthalene sulphonic acids, including Diamidonaphthalene carbonic acids.

Dihydroxynaphthalenes including Trihydroxynaphthalenes.

Dihydroxynaphthalene sulphonic acids, &c.

Amidohydroxynaphthalenes, &c.

Amidohydroxynaphthalene sulphonic acids, &c.

Bibliographic references.

Table on the Di- and Trichloronaphthalenes, Naphthalene di-, tri-, and Tetrasulphonic acids and Nitronaphthalene sulphonic acids.

JAHRESBERICHT ÜBER DIE LEISTUNGEN DER CHEMISCHEN TECHNOLOGIE, mit besonderer Berücksichtigung der Elektrochemie und Gewerbestatistik für das Jahr 1895. Von Dr. FERDINAND FISCHER. Mit 226 Abbildungen. Verlag von Otto Wigand, Leipzig, Germany. 1896. H. Grevel and Co., 33, King Street, Covent Garden, London. Price 2*l.*

THE progress and position of Chemical Technology up to the end of the year 1895 are treated of in this Annual Report. Trade statistics, with more special reference to the German Empire, are also given. The Jahresbericht for 1894 contained 1150 pages, whereas the present one contains 1140 pages. Its complete Alphabetical Indexes for authors and subject-matter, extend from page 1111 to 1198, i.e., over 57 pages. An Index of German Patents completes the volume, and it fills nine pages. The text is illustrated with 226 engravings referring to plant and apparatus. The following is a synopsis of the subjects treated of in the volume, the extent of each group and its treatment being indicated by the number of pages filled. (In this connection it may be mentioned that the Table of Contents, itself a complete epitome, covers close upon 35 pages.) GROUP I. CHEMICAL TECHNOLOGY OF FUEL (pages 5 to 108). II. CHEMICAL METALLURGY (pages 109 to 284). III. ELECTROCHEMISTRY (pages 285 to 591). IV. CHEMICAL MANUFACTURES, INORGANIC (pages 392 to 541). V. CHEMICAL MANUFACTURES, ORGANIC (pages 542 to 731). VI. GLASS, POTTERY, CEMENTS, ARTIFICIAL STONE (pages 732 to 782). VII. FOODSTUFFS (pages 783 to 952). VIII. CHEMICAL TECHNOLOGY OF FIBRES (pages 953 to 1041). IX. OTHER INDUSTRIES CONNECTED WITH ORGANIC CHEMISTRY (pages 1042 to 1124). X. APPARATUS (pages 1125 to 1140). It was remarked in the notice of the Jahresbericht for 1894, that the group on Electrochemistry had been added for the first time there. The subject filled 85 pages. In the present issue, for 1895, this subject has 106 pages devoted to its treatment.

Trade Report.

TARIFF CHANGES AND CUSTOMS REGULATIONS.

ARGENTINE REPUBLIC CUSTOMS LAW FOR 1896.

See *Board of Trade Journal* for May, p. 554.

SWEDEN.

Tariff Modifications.

Yeast.—The present duty of 25 öre to be reduced to 20 öre per kilo.

Explosives (Sprängämnen).—The following new duties to be imposed:—

Guncotton (bomullskrut), 30 öre per kilo.

Smokeless powder (barksvagt), 50 öre per kilo.

Other explosives (andra olag), 25 öre per kilo.

Common powder (krut) to remain as before with the duty of 12 öre per kilo.

These new duties will come into force on the 1st of January 1897, unless the Government should in the meanwhile decide otherwise.

UNITED STATES.

Customs Decision.

Formaldehyd, or beer preservative, is to pay duty at the rate of 25 per cent. *ad valorem* under paragraph 60 of the Act of August 28, 1891.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

OPENINGS FOR BRITISH TRADE IN THE WESTERN UNITED STATES.

Board of Trade Journal, May 1896, 584.

A memorandum, dated April 13 last, has been received at the Foreign Office from Mr. A. G. Vansittart, Her Majesty's Consul at Chicago, which calls attention to some articles of commerce which should, in the interests of British trade, be watched by British merchants. The memorandum states that there is a good market in the western parts of the United States for earthenware, crockery, china, glass-ware, and enamelled ware. Although the imports from Great Britain are steadily increasing, still they do not increase as fast as the country develops, and cheap American products are being used where British-made goods, if the same were made known, might be utilised. Many large firms in Kansas City, Leavenworth, Topeka, Atchinson, St. Joseph, Lincoln, Omaha, Sioux City, and Denver would probably buy if an opportunity were given. This would appear to be a favourable moment for pushing the above class of goods forward in the western country.

In 1894, Kansas City received from Great Britain 6,000/ value of the above-named goods; in 1895 the value had increased to 15,871/. In 1894, Omaha received 422 crates, and in 1895 as much as 612 crates. The orders are increasing, but there appears to be room for larger ones.

It should also be pointed out that British merchants should observe more closely the market in the following articles, viz.:—Linen, carpets, linoleum, salt, saltpetre, cotton goods, woollen goods, knit goods, caustic soda, plate-glass, quick-silver, and fuller's earth. Mr. Burrough, Her Majesty's Vice-Consul at Kansas City, is of opinion that the trade in the above goods, in his district at least, could be increased materially.

The importation of tin (? plate) from the United Kingdom to Kansas City and Omaha is falling off rapidly this year so far, and American tin (? plate) is coming in and taking the place of the British article. The following table shows the amount of tin used annually in the different cities:—

	Lb.
Kansas City	14,000,000
Omaha	8,000,000
St. Joseph	4,000,000
Denver	3,000,000

One firm in Kansas City uses about 7,000,000 lb. per year, and there are some 10 firms using tin in large quantities in the west. The British merchant should be

able to increase his business, for tin will probably increase as fast and in the same ratio as the packing-house business does.

The following amounts were imported from Great Britain to the cities as named:—

Kansas City, in 1894, 4,825,919 lb.; in 1895, 6,774,851 lb.

Omaha, in 1894, 4,500,000 lb.; in 1895, 4,980,000 lb.

St. Joseph, in 1895, 2,000,000 lb.

Denver, in 1895, 3,102,000 lb.

As regards Portland cement, complaints are made from the above four cities that the British article is too much mixed, and that its diminution is due to that cause. On the other hand, German and Belgian Portland cements are giving universal satisfaction, and their trade is increasing. Of imported cements used in the western cities, 70 per cent. is German, 20 per cent. Belgian, and only 10 per cent. British. More cement is being used every year.

ARGENTINE REPUBLIC: SHEEP SCAB AND SHEEP DIPS.

U.S. Consular Reports, April 1896, 519—522.

The U.S. Consul at Buenos Ayres reports as follows:—

The great plague of the wool growers of the Argentine Republic is the sheep scab (*scabie oralis*). It has spread to all parts of the country, and there is not a sheep estancia, or cabaña but suffers more or less from its presence.

Thus far, nothing in the way of laws going radically to the extirpation of the disease has yet been enacted. The cost to farmers of sheep dips will be appreciated when it is remembered that the number of sheep in the Argentine Republic is now estimated to be 80,000,000.

When it is borne in mind that not merely is the wool ruined by scab, but that the carcass itself is rendered unfit for food when the sheep is thus diseased, the absolute necessity on the part of the sheep farmer of curing scabby flocks will be better understood. Thus the amount expended annually for sheep dips and scab specifics goes on increasing as the flocks and shipments increase. For 1885, the value of the importations amounted to 150,261 dols., and for 1894, to 840,551 dols., an increase in ten years of 650,290 dols. In 1890, the number of tons imported was 1,078; in 1894, it was 2,262, an increase in five years of 1,484 tons. The following table shows the importations by countries for the years named:—

Country.	1891.	1892.	1893.	1894.
	Dols.	Dols.	Dols.	Dols.
Germany	38,826	80,808	101,172	26,585
Belgium	29,000	45,195	27,964	44,842
United States	55,589	32,604	45,126	8,799
France	14,830	3,702	107	929
Great Britain	151,889	671,079	353,121	84,976
Italy	47,800	50,525	30,762	59,364
Uruguay	6,215	12,040	715	4,577
All other countries	2,072	15,945	2,423	10,488
Total	337,852	918,808	561,480	810,551

For the first nine months of the present year the importations have already amounted to 2,980 tons, valued at 745,260 dols., thus showing that the business of supplying the sheep farmers of the Argentine Republic with specifics for the cure of scabby flocks steadily increases with the increasing number of sheep.

It will be observed that a very large proportion of the specifics for scab are imported from Great Britain. The United States, of late years, has contributed but very little to the quantities imported. The ingredients are as cheap in the United States as in England, if not cheaper. Most of that which is shipped from the United States is some preparation of tobacco, and generally comes in barrels. As a general thing, that from England is either a powder to be dissolved in water or a liquid solution which comes in iron kits or drums, holding from 1 to 5 gallons, and is diluted to the proper strength when it is to be used.

The Argentine Government allows all preparations for curing scab to be passed through the Custom-houses free of duty. It is true that, in 1894, a duty of one-fourth of 1 per cent. *ad valorem* was put upon all such specifics, but it was omitted in the tariff which is at present in force, and

it will be omitted, in all probability, from the tariff for 1896.

American Dips.—If there are those in the United States who contemplate engaging in the preparation and shipment of sheep dips to the Argentine Republic, they should first be sure that they have a first-class article to put upon the market; otherwise, while they may succeed in selling it once, its demerits or disadvantages will soon come to be understood. It is only the good, reliable specifics that can be expected to find steady purchasers among sheep farmers; but reliable articles will soon secure a general demand. There are already such articles on sale here, having stood the tests and trials of many years. The most effective way to get a trial here is by sending a man who understands the business along with a consignment of the dip. Having a direct interest in its success, he will not be slow in illustrating to the sheep men what it can do. He would then be in a condition to secure an active and reliable agent here, who understands the trade and the people, and who, by keeping the material always in stock, would be able to supply all demands for it at once, without waiting for an order to be sent to the United States to be filled. Or, if the dip, upon trial, is found to fulfil all the conditions of an infallible specific, manufacturers of the article might be able to find houses here who would buy on their own account, provided they could obtain as satisfactory terms and conditions as those offered by European shippers. So far as the price is concerned, of course that must necessarily depend upon the cost of the ingredients and the expense of compounding them, and manufacturers know at what figures they are able to put their own preparations upon the market. Whether they be of tobacco, arsenic, lime, sulphur, or some other chemicals, the less expensive the material, the cheaper must be the article when prepared for sale. The Custom-house valuation of such specifics is 25 cents per kilo. When it comes in drums the price ranges from 80 cents to 1.25 dols. per gallon, including the drum.

There is always more or less demand for these specifics, for scabby flocks must be taken care of at once, but the general season for administering the dip is just after the shearing is over, as it then acts both as preventive and cure. The special details of the business, however, cannot be anticipated, but must be left for those who buy or sell to arrange for themselves.

GENERAL TRADE NOTES.

THE MINERAL PRODUCTION OF CALIFORNIA IN 1895.

Engineering and Mining Journal, May 16, 1896, 466.

The California State Mining Bureau has just issued in tabular form a statement showing the mineral production of the State for the year 1895. According to its figures the value of the total mineral product of California in 1895 was 22,844,664 dols. against a total of 20,203,294 dols. in 1894, showing the substantial increase of 2,641,370 dols., a considerable part of which was due to the greater production of gold.

The mineral production is divided into four classes. The first is formed by the metallic products, quantities and values of which are shown in the following table:—

Metallic.

Substance.	Customary Measure.	Quantity.	Value.
			Dols.
Gold.....	15,384,318
Silver.....	599,790
Chrome.....	Short Tons	1,740	16,795
Mineral paint.....	..	750	8,425
Quicksilver.....	Flasks	36,101	1,337,131
Manganese.....	Short Tons	880	8,200
Copper (fine).....	Pounds	225,900	21,909
Lead.....	..	1,592,409	49,364
Antimony, ore.....	Short Tons	33	1,485
Platinum.....	Ounces	159	900
Total.....	17,378,308

The most notable increase is that shown in the production of gold; it amounted to 1,763,920 dols. over the production of 1894, and to 3,254,317 dols. over that of 1893.

Next in importance is the output of quicksilver. The mines of that metal are still very actively worked and show a substantial gain in production over 1894, although no new discoveries have been made.

The other mineral products include chrome ore, which was one of the few industries showing a diminished output; antimony, of which a small amount was obtained from the mines in Kern County; lead from Inyo and Mono counties; copper from Amador, Calaveras, and Nevada counties, chiefly obtained in connection with the gold mines; manganese ore and platinum. Of the latter metal 150 ounces are reported which is not assigned to any particular locality, but was obtained in the assay office from refining gold.

The non-metallic substances, which are of considerable importance, are shown in the following table:—

Non-Metallic.

Substance.	Customary Measure.	Quantity.	Value.
			Dols.
Borax.....	Short Tons	5,950	595,900
Coal.....	..	79,859	193,790
Salt.....	..	53,031	180,576
Asbestos.....	..	25	1,000
Gypsum.....	..	5,158	51,011
Magnesite.....	..	2,200	17,000
Soda.....	..	1,900	47,500
Total.....	1,056,780

The third division of the Bureau's report includes the hydrocarbons and gases. The production of petroleum in California has increased very considerably, the discoveries of new oil territory in and around Los Angeles some two years ago having been utilised by the boring of numerous wells, so that the district is now actively worked. Asphalt and bituminous rock are mined in increasing quantities, as the value of the California product is recognised.

Hydrocarbons and Gases.

Substance.	Customary Measure.	Quantity.	Value.
			Dols.
Asphaltum.....	Tons	25,525	170,500
Bituminous rock.....	..	38,421	121,586
Natural gas.....	112,000
Petroleum.....	Bbls.	1,245,339	1,000,235
Total.....	1,404,321

Caoutchouc..... Cwt.	25,192	31,788	261,039	341,940
Gum:—			£	£
Arabic.....	1,960	10,813	13,476	32,019
Lac, &c.....	11,070	16,011	79,548	82,816
Gutta-percha.....	3,468	3,623	24,669	31,109
Hides, raw:—			£	£
Dry.....	38,068	35,912	73,951	88,601
Wet.....	57,923	42,920	108,848	97,245
Ivory.....	930	1,077	37,651	41,371
Manure:—			£	£
Gaïno..... Tons	6,384	215	59,203	1,405
Bones.....	7,081	5,918	30,503	22,926
Nitrate of soda.....	8,978	11,173	399,759	90,117
Phosphate of lime.....	30,129	35,467	56,949	49,505
Paraffin..... Cwt.	70,182	59,528	79,283	51,126
Linen rags..... Tons	1,906	1,739	29,621	15,757
Esparto.....	12,823	14,981	53,042	64,779
Pulp of wood.....	21,509	24,497	111,591	118,056
Rosin..... Cwt.	108,940	196,319	24,194	59,576
Tallow and stearin.....	191,097	290,828	222,911	217,013
Tar..... Barrels	1,752	846	933	411
Wood:—			£	£
Hewn..... Loads	133,281	223,926	229,281	111,389
Sawn.....	138,590	229,466	321,424	543,753
Staves.....	4,944	7,757	12,322	42,244
Mahogany..... Tons	3,382	3,297	27,681	31,658
Other articles..... Value £	798,379	824,147
Total value.....	3,605,266	3,324,950

Besides the above, drugs to the value of 77,811*l.* were imported, as against 69,869*l.* in April 1895.

IMPORTS OF OILS FOR MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Cocoa-nut..... Cwt.	15,828	14,861	17,479	19,880
Olive..... Tons	1,926	2,498	64,040	77,521
Palm..... Cwt.	85,929	81,922	91,131	84,315
Petroleum..... Gall.	14,907,872	14,389,459	299,777	268,564
Seed..... Tons	4,176	3,175	82,046	61,908
Train, &c..... Tons	994	1,577	17,863	26,232
Turpentine..... Cwt.	13,758	2,517	14,271	1,584
Other articles..... Value £	76,302	88,251
Total value of oils.....	664,439	628,705

EXPORTS OF METALS (OTHER THAN MACHINERY) FOR
MONTH ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Brass..... Cwt.	9,368	9,567	36,290	37,469
Copper:—			£	£
Unwrought.....	41,230	47,516	93,668	113,373
Wrought.....	29,010	25,954	72,119	72,275
Mixed metal.....	32,012	26,045	63,429	56,959
Hardware..... Value £	149,540	162,803
Implement.....	107,906	108,374
Iron and steel..... Tons	225,459	289,333	1,506,329	1,967,985
Lead.....	2,941	3,002	36,047	39,333
Plated wares..... Value £	24,886	21,215
Telegraph wires.....	35,544	23,065
Tin..... Cwt.	9,337	9,469	32,911	30,406
Zinc.....	18,878	18,860	12,292	11,916
Other articles..... Value £	61,192	71,420
Total value.....	2,232,983	2,716,535

EXPORTS OF DRUGS AND CHEMICALS FOR MONTH
ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Alkali..... Cwt.	184,611	164,040	120,488	111,739
Bleaching materials.....	114,718	93,619	42,186	31,974
Chemical manures..... Tons	264,87	25,448	161,131	130,549
Medicines..... Value £	88,815	88,653
Other articles.....	267,938	352,241
Total value.....	675,558	715,256

EXPORTS OF MISCELLANEOUS ARTICLES FOR MONTH
ENDING 30TH APRIL.

Articles.	Quantities.		Values.	
	1895.	1896.	1895.	1896.
Gunpowder..... Lb.	624,800	513,400	13,927	13,780
Military stores..... Value £	186,862	120,471
Candles..... Lb.	1,585,400	1,710,700	26,880	26,997
Caoutchouc..... Value £	107,051	98,234
Cement..... Tons	36,115	30,150	57,775	49,174
Products of coal..... Value £	167,405	162,811
Earthenware.....	116,448	133,420
Stoneware.....	13,495	17,825
Glass:—			£	£
Plate..... Sq. Ft.	87,010	167,563	4,534	7,287
Flint..... Cwt.	8,465	6,599	16,140	16,283
Bottles.....	56,849	61,488	27,028	30,024
Other kinds.....	16,221	21,399	15,395	16,246
Leather:—			£	£
Unwrought.....	11,527	9,908	100,197	92,447
Wrought..... Value £	25,926	27,601
Seed oil..... Tons	5,821	5,138	111,514	97,068
Floorcloth..... Sq. Yds.	1,962,500	1,922,390	79,713	79,337
Painters' materials..... Value £	131,274	139,563
Paper..... Cwt.	82,647	81,130	131,552	129,145
Rags..... Tons	4,024	4,012	23,871	22,312
Soap..... Cwt.	57,732	51,895	58,416	59,041
Total value.....	2,703,189	2,723,558

Monthly Patent List.

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete Specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

I.—PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

8250. T. O'Hara and J. R. and T. Ashmore. Improvements in or relating to valves. April 20.

8273. J. G. Nash and J. M. Borrow. An improved process of and apparatus for preventing the incrustation in boilers. Complete Specification. April 20.

8805. C. H. C. Rudd. Improvements in cocks or taps for use with various chemical corrosive fluids. April 27.

8888. J. B. Readman. Improvements in apparatus for obtaining cyanides. April 28.

8964. O. Imray.—From D. Graham. Improvements in electrical furnaces. April 28.

9084. J. Longshaw. Improvements in vacuum apparatus for frying, distilling, concentrating, and other like purposes, and in the method of and means for obtaining and maintaining vacuum therein. April 30.

9098. J. Maynes and C. L. Waterhurst. Apparatus for the separation of gases. April 30.

9127. M. Douane. Improvements in apparatus for producing cold by means of volatile liquids. April 30.

9475. H. Gerling. An instrument to be employed in skimming molten iron and the like. May 5.

9557. H. Herzog. Improvements in or connected with the overflow pipes of distillation and absorption columns. Complete Specification. May 5.

9560. A. H. Wethey. Improvements in calcining furnaces. Complete Specification. May 5.

9709. R. H. F. Finlay. Improved apparatus for removing solids from vacuum and other pans. May 7.

9775. E. E. Heyliss and C. G. Oppermann. The H. and O. filter funnel for rapidly increasing the filtering of tinctures, decoctions, infusions, and other liquids. May 8.

10,177. J. E. Tolson. A new or improved retort for engendering gases. May 13.

10,431. J. Fielden. Improvements in apparatus for drying wool and other fibrous material. Complete Specification. May 15.

10,547. C. H. C. Rudd. Improvements in diaphragm and disc valves for chemical, corrosive fluids, gases, &c. May 16.

10,609. F. Espir.—From W. C. Jack. A material for coating pipes and vessels to lessen conduction of heat to or from their interior. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.*

1895.

12,383. E. Hart. Improvements in condensing and cooling apparatus for acid vapours. May 7.

12,528. C. Linde. Process and apparatus for liquefying gases or gaseous mixtures and for producing cold, more particularly applicable for separating oxygen from atmospheric air. May 20.

1896.

3575. A. J. Boulton.—From M. W. Judell. New or improved heating or cooling agent. May 13.

3859. A. Ludwig.—From S. Moser. Improvements in apparatus for drying vegetable and animal matter. April 29.

5833. J. D. Morel. Improvements in mechanism for cleaning or removing the burrs, thorns, and other impurities from wool, cotton, and other fibrous substances. May 6.

6318. J. F. Lester. Apparatus for treating vegetable and animal fibre with liquids. May 6.

6749. H. Krack. Cooling apparatus for liquids. May 7.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

8247. M. E. Solon and Maquis Bibbero. The Bunsen retort superheating gas-burner. April 20.

8304. C. Bourquin, J. Besson, and P. H. Pute-Cotte de Reneville. Improvements in the manufacture of briquette fuel. Complete Specification. April 20.

8384. B. H. Thwaite. Improved process and plant for generating combustible gases. April 21.

8402. C. D. Jenkins. Improvements relating to the preparation of peat for fuel and to apparatus therefor, and for analogous purposes. April 21.

8509. P. G. de Schodt. New or improved system and means of illuminating and heating applicable with gas and mineral oils. Complete Specification. April 22.

8704. F. L. Perken, E. T. Perken, and A. Rayment. Improvements in or relating to apparatus for producing acetylene gas or the like. April 24.

8807. A. Kohler. Gas lighting by means of carburating elements. April 27.

8861. O. Imray.—From E. Rousseau. Improvement in apparatus for generating, purifying, and liquefying acetylene. April 27.

9037. J. Browne and J. Rice. Improvements in and connected with the quenching and conveying of coke from gas retorts, also applicable to quenching and conveying coke and ashes from other furnaces. April 29.

9047. T. D. Farrall. Method of and apparatus for heating by electricity. April 29.

9184. J. T. E. P. Cosson. New process for the decomposition of water into its component gases and apparatus therefor. May 1.

9244. W. Nicholls. Improvements in the manufacture of incandescence bodies for illuminating purposes. May 1.

9316. C. E. Botley and C. F. Botley, jun. Improvements in and relating to the treatment of gas for illuminating and other purposes. May 2.

9499. S. Diplock and W. T. Lalonde. Improvements in the combustion of gases or other illuminants. May 5.

9599. R. Bradshaw. Improved artificial fuels. May 6.

9630. C. Coppeaux. Method and means or apparatus for facilitating the combustion of acetylene gas. May 6.

9681. H. L. P. Boot. An improved method of street lighting by glow lamps. May 7.

9861. E. Hutter. Improvements in burners for use with acetylene gas. May 8.

9862. E. Hutter. Improvements in apparatus for liquefying acetylene and like gases. May 8.

9922. J. Sibley. Improvements in apparatus for making, lighting, and heating gas. Complete Specification. May 9.

10,372. E. Andreoli. Improvements in apparatus for the production of ozone. May 14.

10,407. R. Goodwin. A portable lamp standard to produce and burn acetylene gas or acetylene and carbonic acid gas combined. May 15.

10,480. P. C. Frewin. Improvements in generators for producing acetylene gas. May 15.

10,568. V. I. Feeny.—From P. Carmien, A. Yvonnet, and M. Billion. Automatic gas-producing apparatus and burner therefor. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

2224. J. Moeller. An improvement in illuminant appliances for incandescence gas lights. May 7.

10,414. W. P. Gibbons and G. B. A. Gibbons. Improvements in apparatus for charging gas retorts. May 6.

11,082. G. Haycraft. Improvements in machines or presses for use in the manufacture of artificial fuel or briquettes. May 6.

11,887. H. Gardner.—From La Société Française de l'Éclairage. An incandescent irradiator for gas without the preliminary admixture of air. April 29.

11,966. A. B. Willway. Improved construction and arrangement of container for ether saturation of oxygen for limelight. April 29.

12,344. J. H. Exley. Apparatus for generating acetylene gas. May 7.

24,015. C. Wurster. Improvements in the combustion of carbohydrates of high boiling point in incandescence burners and apparatus therefor. April 29.

1896.

322. J. C. Bayley. An improved apparatus for generating, storing, and purifying acetylene and like gases. May 6.

2563. W. Schoning. Process for producing fuel from turf or peat. April 29.

3982. E. J. Shaw. Incandescent gas lamps or burners. May 6.

4674. S. S. Bromhead.—From A. Niel. A self-regulating gas generator. April 29.

5279. G. Ragot. Improvements relating to the production of acetylene gas and to the utilisation of the same for lighting purposes. May 13.

5423. R. J. Seblight. Improvements in and relating to the promotion of combustion in furnaces, fireplaces, lamps, burners, and the like. April 29.

7242. W. C. Clarke. Method of and apparatus for generating acetylene. May 6.

7243. W. C. Clarke. Method of generating illuminating gas. May 6.

7429. J. B. de Lery. Mantles for incandescent gas and oil lamps. May 13.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

APPLICATIONS.

8718. E. Morrice. Nathaline. April 25.

9944. A. C. Thomson. Improvements in vertical retorts for the destructive distillation of carbonaceous substances. May 11.

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

8582. H. H. Lake.—From Lepetit, Dollfus, Gausser, and Co. Improvements in and relating to the manufacture of dyestuffs and tanning extracts. April 23.

8770. H. Imray.—From The Basle Chemical Works, Bindschedler. Manufacture of alkyl glycolic acid derivatives of paramidophenol ethers. Complete Specification. April 25.

8857. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Improvements in the manufacture of colouring matters of the rosinduline series. April 27.

8860. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Process for discharging para-nitro-aniline red fabrics, white and coloured, and manufacture of a discharging colour therefor. April 27.

9122. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The production of azo colouring matters on fibre. April 30.

9343. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of basic disazo dyestuffs. May 2.

9477. L. P. Marchlewski, E. S. Wilson, and E. Stewart. Improvements in the production of dyes. May 5.

9912. E. Ritter von Porthelm. Process for producing black azo dyestuffs on the fibre. Complete Specification. May 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

5796. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of dyestuffs. March 4.

5797. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture of colouring matters. March 12.

5861. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring matters. March 4.

10,669. H. H. Lake.—From Farbwerke Mülheim. Manufacture of colouring matters. April 29.

12,094. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of purpurine-sulpho-acid. April 29.

12,162. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Process for the partial or total destruction of beta-naphthol on the fibre by oxidation by means of persulphates. April 29.

12,465. A. Zimmermann.—From The Chemische Fabrik auf Actien vormals E. Schering. Production of *y*-oxyperidine carbo acids and derivatives therefrom. May 6.

12,607. O. Imray.—From The Farbwerke vormals Meister, Lucius, and Brüning. Manufacture of new brown to black azo colouring matters dyeing direct on cotton. May 7.

12,667. H. E. Newton.—From The Farbwerke vormals F. Bayer and Co. The manufacture or production of derivatives of hydroxyanthraquinone. May 7.

17,160. W. Majert. Process for obtaining pyrocatechin mono-acetic acid. May 6.

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

8323. C. M. White.—From The Electro Waterproofing and Dye-Fixing Company. A new or improved process of electrically treating fabrics for waterproofing and other purposes. Complete Specification. April 21.

8517. A. R. Waddell. Improvements in or relating to the treatment of rhea and other fibrous materials. April 22.

9877. T. Illingworth. A new or improved process for stopping or reducing the liability of certain fabrics to shrink. May 9.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

11,546. B. J. B. Mills.—From V. Crepet. A new or improved process for the decoration or ornamentation of velvets, plushes, and other pile fabrics. May 6.

12,218. R. W. E. MacIvor and J. Chester. Improvements in the treatment of rhea or ramie (*boehmeria tenacissima*) and china grass (*boehmeria nivea*). April 29.

13,626. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. The manufacture or production of colouring matters. May 20.

13,947. C. D. Abel.—From The Actien Gesellschaft für Anilin Fabrikation. Manufacture of direct-dyeing azo colouring matters. May 7.

14,633. H. H. Lake.—From K. Oehler. New brown azo dyestuffs and method of producing the same. May 7.

1896.

5532. C. E. Puller and A. Biemann. Improved process for loading silk and silk waste. May 7.

7405. C. Effros. Improvements in the treatment of vegetable fibre. May 13.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

8297. W. H. Caldwell. Improvements in the bleaching of paper pulp and other fibrous materials. April 20.

8311. L. C. G. Lesage. An improved process of and apparatus for use in colour-printing. April 20.

8318. C. M. White.—From The Electro Waterproofing and Dye-Fixing Company. Improvements in the art of fixing dyes in fabrics. Complete Specification. April 21.

8491. B. Thies. Process of and apparatus for bleaching, dyeing, washing, &c. spun fibres and stuffs of every kind. Complete Specification. April 22.

9767. J. Reixach and F. Blamford. Improvements in dyeing pile fabrics. May 7.

9941. T. Parry-Jones. Liquid process for woollen bleaching. May 11.

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

8288. O. Imray.—From La Société Christiania Minnekompani. Process for the production of ammonia and other compounds of nitrogen and hydrogen, also nitrous and nitric acids. April 20.

8634. S. A. Sadler and R. H. Wilson. A new process for the manufacture of chlorine. April 24.

8652. C. F. Wulffing. Improvements in the manufacture of oxalic acid. April 24.

8826. J. A. Wanklyn and W. J. Cooper. An improvement in the manufacture of cyanides. April 27.

9544. P. Jensen.—From D. Cappelen and H. Cappelen. Process for purifying chlorine gas. Complete Specification. May 5.

10,252. D. A. Peniakoff. A process for obtaining an or extracting caustic alkalis from alkaline aluminates, and hydrates of barium and alumina from barium aluminate. May 13.

10,574. E. Cuyllits. Process for utilising phosphate ore deficient in phosphorus with a view to produce monocalcic superphosphates of high standard and, in connection with the said process, a special kind of drying-oven. May 16.

10,577. A. Wolf and W. S. Blythe. Improvements in the manufacture of chlorates of potassium and sodium. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8449. C. Hoepfner. Improvements in and relating to the manufacture of solutions of zinc chloride and other metal chlorides. April 29.

10,476. J. Raschen and J. Brock. Improvements in the manufacture of cyanides and ferrocyanides from sulphocyanides and the recovery of by-products. May 20.

10,956. J. Raschen and J. Brock. Manufacture of cyanides and ferrocyanides from sulphocyanides and the recovery of by-products. May 20.

1896.

1729. F. Perez. Improvements in or relating to the manufacture of salt. May 7.

7123. A. von Siemens. Process for working metallic sulphides. May 20.

VIII.—GLASS, POTTERY, AND ENAMELS.

APPLICATIONS.

8642. G. B. Ford. Application of ceramic colours to the surface of tiles by means of a composition roller. April 24.

9078. W. Stranbe and The Actien-Gesellschaft Maschinenfabrik Landsberg-on-the-Lech. Improvements in presses for the manufacture of glass wares. April 30.

9601. E. W. Brock. An improved method of decorating glass for leaded lights and similar goods. May 6.

10,474. W. West. Improvements in apparatus for the manufacture of moulded clay, earthenware, and ceramic articles. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

13,104. W. Illingworth. Machines for casting pottery ware. May 13.

13,522. W. Illingworth. Improvements in or applicable to ovens or kilns for firing pottery ware and the like. May 13.

1896.

5622. C. Mayer. Improvements in and relating to pottery ware and like glaze-firing furnaces and kilns. April 29.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

8314. L. Preussner. Improvements in the production of artificial stone. April 20.

9100. J. C. Nichol. Improved material to be used as a substitute for wood, and to be known as "fabricoid." April 30.

9556. R. H. Davis. Improvements in the manufacture of fireproof buildings. May 5.

9838. J. Wilkinson. New or improved manufacture of compositions suitable for use as building materials for architectural and other purposes. Complete Specification. May 8.

10,532. P. J. Neate. Improvements in kilns for burning Portland cement, clinker, or substances requiring similar treatment. May 16.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

11,627. W. Stark. Manufacture of cement. May 6.

11,586. H. L. Doulton and A. J. Smith. Manufacture of tiles. May 7.

12,242. E. M. Arndt and G. de Bruyn. Manufacture of artificial stone. April 29.

12,382. J. J. Bloomfield. Manufacture of plaster. April 29.

13,073. C. A. Allison.—From The Marguctelle Mosaic Company. An improved substitute for wood and the like. May 13.

14,187. A. Hirsch. Manufacture of vitreous artificial stone. May 13.

21,537. J. Holroyd. Manufacture of terra-cotta and like blocks for building purposes. May 13.

1896.

3799. W. P. Thompson.—From La Société Anonyme la Neo-Litho. Improvements in the manufacture of artificial stone and apparatus therefor. May 13.

3800. W. P. Thompson. From La Société Anonyme la Neo-Litho. Manufacture of artificial stone. April 29.

5386. O. Kleinberger. Building bricks. May 6.

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

8331. F. W. Popp. An improved metal. April 21.

8368. T. Doherty and P. D. Crear. Improvements in the process of melting iron. Complete Specification. April 21.

8595. T. Smith. Improvements in or connected with readily fusible metal or alloy and the manufacture of articles therefrom, or from other metals or alloys. April 23.

8690. S. O. Cowper-Coles and S. Learoyd. Improvements in the manufacture and production of metallic alloys. April 24.

8781. C. T. J. Vautin. An improved process for the reduction of composite lead and zinc ores. April 25.

8882. A. Tracy. An improved method of combining hard metal and soft metal or other material to form non-slipping and non-extensible floor covering and stair nosing. April 28.

8907. T. Twynam. Improvements in the production of an alloy of iron and an alkaline metal for use in the manufacture of steel from phosphoric pig-iron and for other purposes. April 28.

8946. H. H. Lake.—From Hawkins Steel Co., Lim. Improvements relating to the purifying and refining of iron and apparatus therefor. Complete Specification. April 28.

8959. J. D. Grey. Improvements in the method of and apparatus for preparing sheet iron and steel in the manufacture of tin andterne plates, or for galvanising. Complete Specification. April 28.

8967. S. Vivian. Improvements in apparatus for the recovery of gold, silver, and other precious metals. April 28.

8998. C. J. Ellis. Improvements in separating solutions containing precious metals from clayey, slimy, or adhesive materials. April 29.

9041. S. O. Cowper-Coles. Improvements in the treatment of tin ore and tailings containing tin, and the obtaining of metallic tin therefrom. April 29.

9123. F. Ellershausen. An improved process for the treatment of refractory ores. April 30.

9220. C. T. J. Vautin. An improved process for the reduction of argentiferous or non-argentiferous complex sulphide ores of lead and zinc. May 1.

9232. F. B. Aspinall and The Electrical Oil Refining Co., Lim. Improvements in the treatment of cotton-seed and other oil. May 1.

9388. C. A. Burghardt and G. Rigg. Improvements in the method of and means for obtaining copper from copper ores. May 4.

9408. E. Rousseau. An improved method for galvanising iron. May 4.

9514. W. Kirkham and D. Evans. Improvements in the method of casting ingots, and in ingot moulds and appliances connected therewith. May 5.

9524. J. A. Bruce-Fraser. A new or improved process for extracting gold and other metals from their ores, especially applicable to the treatment of refractory ores. May 5.

9552. W. P. Thompson.—From W. E. Harris. A new or improved method of and apparatus for treating and annealing sheet metal. Complete Specification. May 5.

9577. J. H. Pollok. An improved method of treating auriferous slimes. May 5.

9656. The Improved Electric Glow Lamp Syndicate, Lim.—From C. Schwabe. An improved process for depositing metals on silver coatings. May 6.

9772. J. Lyle. Improved method and apparatus for concentrating or separating and recovering metals and metallic ores from metalliferous substances. May 8.

10,097. J. Jones. An improved method or process for the treatment of gold-bearing antimony ores. Complete Specification. May 12.

10,494. J. R. Wyld, J. W. Kynaston, and J. Brock. Improvements in the extraction of zinc from ferruginous liquors, specially applicable to the treatment of the spent liquors of copper works. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8328. C. Hoepfner. Improvements in and relating to the treatment of ores or materials containing zinc, lead, and silver. April 29.

8376. A. Schmidt. Improvements in and relating to the extraction of gold and silver from their ores. April 29.

10,865. W. J. Clapp and J. F. Wake. Improvements in furnaces, and apparatus for, and in the method of manufacturing and purifying the waste products from blast and other furnaces, cupolas, and for other purposes. May 20.

12,018. L. Mond. A process for reducing certain metallic oxides by means of amalgams or alkaline metals. May 20.

12,452. H. E. Fry, J. David, and C. le Donx. Improvements in the extraction of lead with silver, gold, or other metals from galena or sulphides of lead and zinc, and from mattes and refractory ores. May 13.

13,536. M. Crawford.—From R. Keek. Improvements in treating slimes from ores of the precious metals. May 20.

1896.

4776. W. H. Bailey. Improvements in and relating to furnaces for heating metal. May 20.

6242. J. Mait. Apparatus for separating and saving gold. May 13.

7272. F. B. Last and J. R. Wright. Improvements in the manufacture of steel. May 20.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

APPLICATIONS.

20,542A. G. Bell and G. W. Bell. Improvements in or connected with apparatus for the electrolytic decomposition of liquids. Date claimed Oct. 31, 1895. Filed May 4.

8410. J. C. Graham. Improvements in the electro-deposition of metals, particularly applicable to the deposition on wires. April 21.

8660. F. W. Schneider. Improvements in the construction of cells for electric accumulators. Complete Specification. April 24.

8666. The Battery and Motor Co., Lim., and H. T. Barnett. Improvements in and connected with battery electrodes. April 24.

8695. W. Majert. Improvements in electrodes for accumulators. Complete Specification. April 24.

8906. L. B. Atkinson and P. G. Treharne. Improvements in the generation of electricity. April 28.

9289. W. E. Heys.—From E. Dumoulin. Improvements in and connected with the electro-deposition of copper. May 2.

9910. A. Schanschieff. Improvements in secondary batteries. May 9.

10,095. P. Schmidt. Improvements in electric batteries. Complete Specification. May 12.

10,267. C. Hoepfner. Improvements in electrodes for galvanic batteries. May 13.

10,349. A. M. Clark. A process of preparing metals for galvanic, electrolytic, and for other purposes. May 14.

10,472. G. A. Grindle. An improvement in active material for secondary voltaic batteries. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

8904. C. L. R. E. Menges. Improvements in primary and secondary battery plates, and in moulds for producing the same. April 29.

12,417. C. H. Weise. Improvements in the manufacture of positive plates for secondary electrical batteries. May 20.

1896.

3091. R. Linde. Improvements relating to the composition of the filling paste of accumulator batteries. May 13.

XII.—FATS, OILS, AND SOAP.

APPLICATIONS.

8289. G. E. G. Terouanne. See Class XVII.

8575. O. Schoning. An improved soap for use in chemical cleaning, laundries, and the like. April 23.

COMPLETE SPECIFICATION ACCEPTED.

1895.

19,960. W. P. Thompson.—From A. des Cressonnières and E. des Cressonnières. Improvements in the mixing and kneading of soap and other like plastic substances, and in apparatus therefor. May 13.

XIII.—PAINTS, PIGMENTS, VARNISHES, RESINS, INDIA-RUBBER, Etc.

APPLICATIONS.

8267. E. W. Barnsley. Improvements in varnish and in the mode of manufacturing the same. Complete Specification. April 20.

8706. W. I. Grylls. Improvements in furniture polish. Complete Specification. April 24.

8981. S. Ganelin. Improvements in the production of a substitute for white lead and of other oxysalts of lead from lead sulphate and lead chloride. Complete Specification. April 28.

9760. W. H. Forester and G. Bland. Improvements in the manufacture of transparent coloured enamels. May 7.

10,181. H. Rudge. Improvements in the manufacture of colours, paints, and stains. May 13.

10,462. A. H. Sandiland. Improvements in the manufacture of white lead. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

13,648. W. W. Cabena. The manufacture of an improved waterproof elastic cement. May 20.

XIV.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

8582. H. H. Lake.—From Lepetit, Dollfus, and Gansser and Co. See Class IV.

9581. F. Humphrey. Antiseptic animal size. May 6.

9582. F. Humphrey. Antiseptic mineral size. May 6.

9583. F. Humphrey. Antiseptic clair colle. May 6.

10,263. A. Levinstein. Improvements in or relating to tanning. May 13.

10,390. A. Levinstein. Improvements in tanning apparatus. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1896.

3715. J. W. Peirson and F. A. T. Moor. Improvements in the art or process of treating skins. May 20.

6410. W. L. Wise.—From Knoll and Co. Manufacture or production of an albumen tannin compound. April 29.

XV.—AGRICULTURE AND MANURES, Etc.

APPLICATIONS.

9789. F. M. Mooney and A. Dickson. Improvement in the manufacture and storing of superphosphates and the like. May 8.

10,109. O. G. Blunden. A new or improved artificial manure or fertiliser, and process for manufacturing the same. May 12.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

11,460. F. Nobbe and L. Hiltner. Improvements relating to the inoculation of soil for the cultivation of leguminous plants. April 29.

12,470. H. Mehner. Improvements in fertilising by the aid of artificial nitrogenous manure. May 7.

XVI.—SUGARS, STARCHES, GUMS, Etc.

APPLICATIONS.

9842. H. Edwards, jun. Improved process for the preparation of milk sugar from skim milk. May 8.

10,330. C. Friedheim and A. Rosenheim. Process for the extraction of white starch and other valuable products from the various species of the sorghum, also applicable to the depriving of other kinds of starch colour. May 14.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

23,555. R. Haddan.—From R. M. y Olivares. A method of producing a vegetable gum adapted to replace gum arabic. May 13.

1896.

7337. J. Perichon. Improved method and apparatus for the treatment of bagasse. May 13.

XVII.—BREWING, WINES, SPIRITS, Etc.

APPLICATIONS.

8289. G. E. G. Terouanne. Manufacture of a charcoal for filtration of spirits and oils. April 20.

9676. J. A. Fawcett. Treatment of materials used in brewing liquors. May 7.

9740. H. Gronwald. Process for preventing the escape of carbonic acid and other volatile matters from beer in casks. Complete Specification. May 7.

9923. H. Gronwald. New or improved process and apparatus for increasing the stability of beer and other liquids containing carbonic acid. Complete Specification. May 9.

10,555. W. P. Knight and E. Cave. An improved purifying material for use in the manufacture of beer and other malt liquors. May 16.

COMPLETE SPECIFICATION ACCEPTED.

1896.

766. E. Davies and H. M. H. Goodfellow. Improvements in the treatment of spent hops for preparing the same for use as a stuffing material, and in machinery therefor. May 6.

XVIII.—FOODS, SANITATION, Etc., AND DISINFECTANTS.

APPLICATIONS.

A.—Foods.

8580. H. Boisselier. A new preparation of tea. April 23.

9908. M. P. Hatschek. Improvements in the production of compressed bakers' yeast. May 9.

B.—Sanitation.

8352. W. H. Higgin. Improvements in the treatment of sewerage. April 21.

10,437. J. T. Norman. Improvements in treating water for the purpose of neutralising or hardening it when acid or soft, together with apparatus relating thereto. May 15.

C.—Disinfectants.

9345. J. Ascough. Improvements in and connected with the manufacture of antiseptic preparations for the preservation of animal and other foodstuffs, for use in the manufacture of butter, for the prevention of or removal of taint from animal food substances, including beef, mutton, bacon, fish, game, and poultry, and for use in the production of beers, light wines, aerated and non-alcoholic and other drinks, and for other purposes. Complete Specification. May 2.

10,067. R. N. Lennox. New process for the use of chlorine and sulphurous acid or their hydrates as disinfectants. May 12.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Foods.

1895.

14,250. O. Inray.—From C. Rach. Manufacture of cocoa compounds. May 20.

22,886. C. M. U. Dable. An improved process for the preservation of fish liver. May 7.

1896.

2176. A. B. Pinto. Preserving meat by the help of electricity. May 13.

1896.

6920. C. L. Villar. Preservation of meat. May 6.

B.—Sanitation.

1895.

8877. P. O'Dowd. Apparatus for the disinfection of sewage. May 6.

11,527. J. J. Hood and A. G. Salamon. An improved means for treating sewage and the like. April 29.

12,067. J. H. Osbourn. Improvements in the method of and apparatus for softening and purifying water. May 7.

21,142. D. Cameron and F. J. Commis. Treatment of sewage and apparatus therefor. April 29.

XIX.—PAPER, PASTRBOARD, Etc.

APPLICATIONS.

8309. H. Thame. Improvements in the manufacture of hollow pulp ware, particularly applicable to buoyant articles. April 20.

8464. H. J. Rogers and W. M. Mordey. Improvements in means and apparatus for the treatment of paper and other fabrics during and after the process of manufacture. April 22.

8672. S. W. Wilkinson and The Grove Co., Ltd. Improvements in the manufacture of substitutes for celluloid. April 24.

9100. J. C. Niehol. See Class IX.

9914. L. Capazza. Improvements in the manufacture of stylographic paper. May 9.

COMPLETE SPECIFICATION ACCEPTED.

1895.

11,546. B. J. B. Mills.—From V. Crepet. See Class V.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATIONS.

8298. K. G. Georgi. Improvements in the manufacture of tabloids. April 20.

8785. W. Bevan. Improvements in the manufacture of arsenic. April 25.

9076. T. P. Sims and W. Terrill. Improvements in the manufacture of white arsenic. April 30.

9521. S. S. Bromhead.—From Gretsch and Mayer. Improvements in the process of making artificial musk. Complete Specification. May 5.

9576. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Improvements in the manufacture of a pharmaceutical substance. May 5.

10,003. J. Y. Johnson.—From C. F. Boehringer and Soehne. Improvements in the manufacture or production of cinnamic aldehyde. May 11.

10,004. E. Fischer. Improvements in the manufacture or preparation of derivatives of xanthine from alkylated uric acids. May 11.

10,005. E. Fischer. A method of preparing alkylated uric acids. May 11.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

12,295. H. E. Newton.—From The Farbenfabriken vormals F. Bayer and Co. Manufacture of a pharmaceutical substance, and in the purification of the same. April 29.

1896.

6157. F. Brunjes. An improved process for the separation of silicic acid from argillaceous substances. May 7.

7692. O. Preu. Manufacture of vanilline. May 20.

XXI.—PHOTOGRAPHY.

APPLICATION.

8394. J. M. Davidson. Improvements in and connected with photography. April 21.

COMPLETE SPECIFICATION ACCEPTED.

1896.

6651. R. E. Schoenfelder and E. Kehle. Improvements in chemical compositions to be used for preparing the surface of suitable material for photographic prints. May 13.

XXII.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

9574. H. Hohendahl. Improvements in or connected with safety fuses. May 5.

9578. J. C. Donnelly. Improvements in apparatus for making lucifer matches or the like. Complete Specification. May 5.

10,403. H. Boyd. A new explosive. May 15.

COMPLETE SPECIFICATIONS ACCEPTED.

1895.

6271. T. Hawkins, S. H. Hawkins, H. Hawkins, and The Donnithorne Gun Patents and Ammunition Co. A new or improved smokeless explosive or gunpowder. April 29.

12,380. J. C. Thompson. Improvements in fuses for explosive projectiles or shells. May 7.

1896.

5687. W. P. Thompson.—From B. T. Steber and W. E. Cook. Apparatus for making lucifer matches or the like. May 13.

7711. M. Wagner. Manufacture of fuses or match-cords. May 20.

THE JOURNAL OF THE Society of Chemical Industry:

A MONTHLY RECORD

FOR ALL INTERESTED IN CHEMICAL MANUFACTURES.

No. 6.—Vol. XV.]

JUNE 30, 1896.

[Non-Members 30/- per annum; Members
21/- per Set of extra or back numbers;
Single Copies (Members only) 2/6.

The Society of Chemical Industry.

Past Presidents:

Sir H. E. Roscoe, M.P., LL.D., V.P.R.S.	1881—1882.
Sir Frederick Abel, Bart., D.C.L., F.R.S.	1882—1883.
Walter Weldon, F.R.S.	1883—1884.
Dr. W. H. Perkin, F.R.S.	1884—1885.
E. K. Muspratt	1885—1886.
David Howard	1886—1887.
Prof. James Dewar, F.R.S.	1887—1888.
Ludwig Mond, F.R.S.	1888—1889.
Sir Lowthian Bell, Bart., F.R.S.	1889—1890.
E. Rider Cook	1890—1891.
Prof. J. Emerson Reynolds, M.D., D.Sc., F.R.S.	1891—1892.
Sir John Evans, K.C.B., F.R.S.	1892—1893.
E. C. C. Stanford	1893—1894.
Dr. T. E. Thorpe, LL.D., F.R.S.	1894—1895.

COUNCIL FOR YEAR ENDING JULY, 1896.

President: Thos. Tyrer.

Vice-Presidents:

Sir F. A. Abel, Bart., F.R.S.	T. Fairley.
Horace T. Brown, F.R.S.	Boverton Redwood.
John Calderwood.	Sir H. E. Roscoe, M.P., F.R.S.
Chas. Dreyfus.	E. C. C. Stanford.
Dr. A. Dupré, F.R.S.	Dr. T. E. Thorpe, LL.D., F.R.S.
Sir John Evans, K.C.B., F.R.S.	Prof. W. A. Tilden, F.R.S.

Ordinary Members of Council:

J. S. MacArthur.	C. C. Hutchinson.
C. A. Paesitt.	Ivan Levinstein.
R. Le Neve Foster.	Sir Robt. Pullar.
W. Douglas Herman.	G. N. Stoker.
David Howard.	Wm. Thorp, B.Sc.
Prof. A. K. Huntington.	Frank Wilson.

With the Chairmen and Secretaries of Sections.

Honorary Treasurer:

E. Rider Cook, East London Soapworks, Bow, E.

Honorary Foreign Secretary:

Ludwig Mond, F.R.S.

General Secretary: Charles G. Cresswell.

Offices: Palace Chambers, 9, Bridge Street, Westminster, S.W.

THE JOURNAL.

Publication Committee:

The President.

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those Members whose names are placed in italics in the list of Council will retire from their respective offices at the forthcoming Annual General Meeting.

Dr. Edward Schunck, F.R.S., has been nominated to the office of President; and Mr. Thomas Tyrer has been nominated Vice-President under Rule II.

Prof. A. K. Huntington, Mr. A. H. Mason, and Mr. G. N. Stoker have been nominated Vice-Presidents under Rule 8; and the Treasurer and Foreign Secretary have been nominated for re-election to their respective offices.

Mr. George Beilby, Mr. Oscar Guttman, and Mr. B. E. R. Newlands have been nominated under Rule 18, and Mr. R. Forbes Carpenter under Rule 19, to fill four vacancies among the Ordinary Members of Council.

A Ballot List and Member's Ticket are enclosed herewith, or have already been despatched under separate cover.

ANNUAL GENERAL MEETING.

The Annual General Meeting will be held in London on the 15th, 16th, and 17th July next. A notice of a modification in the programme is enclosed herewith.

COLLECTIVE INDEX.

A collective index, embracing the whole Journal from the Proceedings of the First Annual General Meeting, 1881, to the close of 1895, is now in preparation, and will be ready in the current year. It will contain both a subject-matter and authors' names portion and will be a volume of about 500 pages, uniform in size with the Journal.

The prices will be as follows:—

To Members (see Rules 25 and 27) who make application with remittance not later than July 31, 1896.....	Each Copy	5s.
To Members (see Rules 25 and 27) who make later application; Libraries, Corporations, and Exchanges on the Society's List, and Past Members (see Rule 30).....	Each copy	10s.
To Subscribers	"	12s. 6d.
To others.....	"	15s.

Notice is hereby given, for the information of members and advertisers, that the advertisement columns of this Journal have been contracted for by Messrs. FYRE and SCOTTISWOODE, the Society's printers and publishers, to whom all communications respecting them should be addressed. The circulation of the Journal is now more than 3,000 per month.

LIST OF MEMBERS ELECTED 23rd JUNE 1896.

- Barratt, J. Treeby, Bronheulog, Mostyn, North Wales, Chemist and Manager.
- Bibby, John, 92, Orrell Lane, Aintree, Liverpool, Student.
- Cubley, G. A., c/o Harrington Bros., Oliver's Yard, 53A, City Road, E.C., Chemist.
- Dempsey, J. C., P.O. Box 210, Watertown, Mass., U.S.A., Chemist.
- Dickenson, F. M., 31, Queen Street, Melbourne, Victoria; and (temp.) c/o Broken Hill Proprietary Company, 3, Great Winchester Street, E.C., Secretary.
- Ewen, Eric D., Port of Spain, Trinidad, B.W.I., Chemist.
- Graves, Walter G., 347, Euclid Avenue, Cleveland, Ohio, U.S.A., Chemist.
- Kingdon, G. Holman, c/o Jos. Crosfield and Sons, Warrington, Technical Chemist.
- Lynn, Arthur H., Pension Schmeltzberg, Fluntern, Zürich, Switzerland, Student.
- Machalski, F. J., 159, North Fifth Street, Brooklyn, N.Y., U.S.A., Technical Chemist.
- Merck, Geo., Corner of University and Clinton Places, New York City, U.S.A., Chemical Manufacturer.
- Rapkin, J. B., c/o Waterlow and Sons, Limited, Skinner Street, Finsbury, E.C., Stationer.
- Reuter, Dr. L., c/o Merck and Co., University and Clinton Places, New York, U.S.A., Chemist.
- Skelton, S. T., 13, Derby Street, Ramsbottom, near Manchester, Chemist (Paper Mills).
- Spoor, J. L., Madras Cement Works, Madras, India, Portland Cement Manufacturer.
- Stiebel, G. L., Graskop, Ltd., Pilgrim's Rest, S.A.R., Manager.
- Stockdale, Albert, c/o R. Dewhurst and Co., Limited, Birstall, near Leeds, Printer.
- Tyrer, A. J., 3, Norwich Road, Forest Gate, E., Student.
- Ullman, Dr. Sabbati E., 167, West 85th Street, New York, U.S.A., Manufacturing Chemist.
- Weicker, Theodore, c/o Merck and Co., New York, U.S.A., Chemical Manufacturer.
- Young, Henry S., c/o Sta. Francisca G.M. Co., Limited, Leon, Nicaragua; and (temp.) 13, Balham Grove, Balham, S.W., Technical Chemist.

CHANGES OF ADDRESS.

- Bailey, Walter P., 1/o Seville; 29, Segismondo Moret, Cadiz, Spain.
- Bamber, H. K. G., 1/o Starcross; 83, Widmore Road, Bromley, Kent.
- Blagden, W. G., 1/o 1; 4, Fenchurch Avenue, E.C.
- Butterfield, W. J. A., 1/o Beckton; Ebor House, Redhill.
- Cameron, Jas., 1/o Pitsea; 3, Bridge Street, Port Sunlight, near Birkenhead.
- Dale, Jas., 1/o Stoke Newington; The Towers, Wallington, Surrey.
- Down, T., 1/o Cardiff; Tharsis Villa, Calstock, Cornwall.
- Duncan, A. W., 1/o Higher Broughton; 42, Trevelyan Street, Eccles, Manchester.
- Dyson, Septimus, 1/o Apperley Bridge; 2, Exchange Place, Middlesbrough.
- Fuerst, W. F., 1/o New York; 32, Carlton Hill, N.W.
- Glover, Wm., 1/o Newcastle; Elektrokemiska Aktiebolaget, Bengtsfors, Sweden.
- Grinshaw, H.; Journals to Sunnyside, Clayton, Manchester.
- Hart, H. W.; Journals to 10, Falcon Avenue, Darwen.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman: R. Messel. Committee: W. J. Dibdin, R. J. Friswell, D. Howard, B. E. R. Newlands, B. Redwood, and T. Tyrer.*

Meeting held Monday, May 4th, 1896.

DR. R. MESSEL IN THE CHAIR.

CHROMATIC PHOTOGRAPHY.

BY E. J. WALL, F.R.P.S.

The title of my notes is sufficiently comprehensive to enable me to briefly glance at all the known methods of reproducing objects with all their colours by photography.

There are three different methods of attaining this end—the first, which may be called the direct method; the second, the interference method; and the third, the indirect. The very first experimenters in photography were naturally struck with the idea of reproducing the colour as well as the form of objects, and the researches of Seebeck in 1810 were followed by Herschel, Becquerel, Poitevin, and others, all of whom endeavoured to obtain the colours directly, that is, by printing from a coloured object on to a salt of silver—the sub-chloride; and Becquerel especially was really successful in obtaining very good reproductions of the solar spectrum in this way. He employed paper coated with silver chloride, which was reduced by the action of light to the violet sub-chloride, and also formed the sub-chloride by direct electrolysis of a silvered plate. Some of his examples are, it is said, in existence at the present time, but they possess really no practical value, for the simple reason no means have been found of fixing the colours—that is to say, when exposed to white light the colours bleach out and turn to the ordinary purple or brown of a common photograph. The reason for this is of course obvious, when I state that any chemical which was applied to these photographs to dissolve out the unaltered silver sub-chloride which had not been affected by light, destroyed the colours, and, of course, if the unaltered chloride was not dissolved away, the light would naturally still act upon it.

Numerous have been the attempts to get over this difficulty, and up to so recent a date as 1892 experimenters were not wanting who still strove to obtain photographs in natural colours by this direct method. There seems, of course, an initial difficulty in inducing one metal like silver to take on or reproduce all the innumerable tints of nature, but Carey Lea, of U.S.A., has been able to prepare allotropic forms of silver, some of which possess extraordinary colours, ranging from violet, through blue, green, yellow, to red, and one similar in appearance to metallic gold, and another soluble in water. It is to me extremely doubtful whether even with further advances this process would become of any commercial value.

The second method, by interference, was the practical outcome of the theoretical reasoning by M. Gabriel Lippmann, of Paris, a well-known physicist, who argued that as we obtained colour by the interference of light, caused by extremely

thin laminae of various substances, it ought to be possible to obtain silver deposited in stratifications so as to give us colour; and in February 1891 his results were shown in Paris, and created no little talk and possibly natural jubilation on the part of the knowing journalist, who immediately hailed it as the long-looked-for philosopher's stone of photography. To enable you to thoroughly understand this process, I am going to explain it in detail, even at the risk of appearing to teach my elders what they already know; but my excuse must be that there may possibly be one present who is not quite posted up on the theory of interference.

You have on the screen here a diagram which represents a ray of light proceeding in the direction of *A d*, the small dots representing the particles of the ether which vibrate backwards and forwards, their several paths being represented by the arrows, and naturally one particle moving as it does at so rapid a rate as 186,000 miles per second jostles its neighbour, and thus we have set up a series of

Fig. 1.

wave-like motions which propagate in the ether the sensation we call light. Each little wave of light has a definite length, and the length of the wave is calculated from any two similar points as regards the axis; for instance, *A c* is a wave length or *b d*, and it is obvious that *a b*, *b c*, or *c d* is exactly half a wave length. Now, it is assumed that colour is due primarily to these wave lengths, and the red has a wave length of about 760,000 tenth metres or microns, one micron being the ten-millionth part of a millimetre.

In this diagram you see merely the same thing, but when the light reached *d* it met with a reflecting surface, and was sent back along the same path; the result was that at *b* and *c* the vibration of the ether molecules was in contrary directions, as shown by the arrows. Now, when we get two forces of equal power pulling in contrary directions it is obvious that the result must be not motion but quiescence,

Fig. 2.

and as light and colour depend upon motion for their existence, it is obvious that we should obtain what are called stagnant waves, separated by nodal points where there would be no light. If such a series of stagnant waves fell upon a film of some silver salt, which was easily affected by light, we ought to obtain on development a series of stratifications or particles of silver deposited at definite distances apart.

The result of this is that when such a result is examined at a particular angle, we have reflected from these deposits of silver, light which has a wave length of just double the distance that these silver particles are apart, and thus we obtain colour; for light which is not of exactly that wave length is not reflected.

I will now explain to you Lippmann's method of obtaining such a result. He prepared an extremely transparent emulsion of silver bromide in albumen or gelatin; the emulsion is so transparent that only when in any appreciable thickness does it show even a faint opalescent appearance. Such an emulsion was coated on glass as thinly as possible, and the glass with its film, when the

latter was quite dry, placed in a dark slide, the film being in contact with very pure metallic mercury, as shown in this diagram: the result was that when this was exposed in the camera, the light passed through the glass and the film,

Fig. 3.

struck the surface of the mercury, and was thence reflected back on itself, and gave rise to the stagnant waves of light, and on development, of course, the strata of silver.

Numerous experimenters have repeated with more or less success this experiment, and we have actually a process by means of which it is possible with three minutes' exposure in sunlight to obtain photographs in natural colours. Lippmann has also been able to obtain by the same apparatus the reproduction of the spectrum in its colours by using a film of bichromated gelatin, when of course no silver was used, but strata of insoluble gelatin would be formed by the action of the light.

The operations in this process, I need hardly say, are extremely delicate, for the thickness of the film itself is not much, if any, more than one-tenth of a millimetre, and in this film there must be no less than about 500 little particles of silver separated by layers of gelatin to give us the violet of the spectrum, for the yellow about 400, and for the red about 330.

The only drawback to Lippmann's interference method of reproducing colours is that the exposure is fairly long, as I have stated—about three minutes—and, further, if more than one copy is required there is no method of reproducing them, and a fresh exposure has to be made for each proof—two facts which at present place the process rather in the domain of the experimental laboratory than in the ordinary studio.

The third and indirect method is the one which at the present time has the most importance commercially, and is the one which I myself have worked at and paid most attention to. It was suggested as early as 1861 by Clerk Maxwell, subsequently by Collen, quite independently, in 1865, and since then, particularly within the last few years, enormous strides have been made, particularly in Germany and America—not in England. Whether it is that we Englishmen are too conservative, or whether there is a general want of real technical training amongst our photo-mechanical printers, I do not know; but the fact remains that in Germany this process is extensively used for book illustration. In America prints such as are on the walls to-night are used by commercial travellers instead of taking round the actual rugs and carpets, and it is used for book illustration also; yet in England there is but one firm that is actually producing the work on any commercial scale.

You all know that what we call white light can be split up into a band of colours called the spectrum, and that we obtain all the innumerable colours of nature by admixture of these spectrum colours; and, further, that although we have the six spectrum colours and the millions of tints in nature formed from them, yet it is assumed that we have what are called three nerve fibrils in our retina, which fibrils respond to three primary colour sensations—red, green, and violet; this theory being called the Young-Helmholtz theory of primary sensations. The indirect

method of reproducing the colours of nature is founded on this theory.

I show you here a diagram which represents the primary colour sensations. 1, 2, and 3 are the spectrum colours which excite the primary colour sensations; *a*, *b*, *c* are the curves which show the relative power of the different spectrum rays to excite the respective fundamental colour sensations. From this you will see that the red sensation

Fig. 4.

is excited by all the rays from red to green, but most powerfully by the orange. The green sensation is excited by the rays from yellow, green, and greenish-blue, and the blue-violet sensation by the blue-green, blue, and violet rays.

There are two methods by means of which we can reproduce objects in colours by this theory, first by using coloured light, and secondly by using pigments. The first process is one which may be looked upon rather as of subsidiary importance, because it is not possible except by means of an optical lantern to show the results to more than one person at a time, and obviously this method is not applicable to the ordinary requirements of everyday commercial life.

To explain to you the production of three-colour prints, such as you see round the room, it is necessary to have recourse to a chart of the spectrum and some explanatory elementary statements. These three-colour prints are produced by using three inks only—red, yellow, and blue, the old artists' so-called primary colours. It may justly be asked, why do we not use the three colours, red, green, and violet, which excite the primary colour sensations? The reason is this. When we use pigments we do not add light to light, but subtract or suppress light; in fact, we make use of the law of absorption.

If we mix red and green light together we get a more or less pure yellow, but if we mix red and green pigments together we obtain a dirty brown. In the same way, if we mix green and blue-violet light we obtain a pure blue, whereas if we mix green and violet pigments we obtain a dirty black. In using pigments we can easily calculate what would be the resultant colour of any mixture. I have said we use the three pigments, red, yellow, and blue; if we place in tabular form these, with the colours they reflect, you will find that it is possible to simulate every colour of the spectrum—

Red	{ Violet. Red. Orange.	Yellow	{ Orange. Yellow. Green.	Blue	{ Green. Blue. Violet.
-----	------------------------------	--------	--------------------------------	------	------------------------------

The red reflects the violet and orange, but red is visually the only colour we see. The yellow reflects orange and green, and yellow is the visual colour. The blue reflects green and violet, but visually appears blue. So that, if we take red and yellow, the colour of the resultant mixture must be orange, because it is the only colour common to both, the red suppressing the green, and the yellow the violet. In exactly the same way, by mixing yellow and blue, the resultant mixture must be green, because this is the only colour common to both; and in mixing red and blue, the resultant colour must be violet. We have thus from our three pigments formed the whole of the six spectrum colours, and the composite colours will be formed by suitable admixture of two or even the three pigments in varying proportions. Black is formed by admixture of all three in equal proportions.

In printing we do not necessarily mix our colours, but lay them down on paper so close to one another that when examined at the distance of normal vision the result is practically a mixture. If this is so, it is obvious that we must have our red ink or pigment in particular places, our yellow also, and also the blue. To make this quite clear, we will take the spectrum as the object to be reproduced, and we will first of all take the red ink.

At the extreme end of the spectrum at A it is obvious that we shall want the red ink in all its intensity, but as we approach the orange we want less red, till in the pure yellow we want no red at all. This can be represented by the diagram as shown here. In the yellowish-green, the green

and blue, we want no red; but again in the violet we want red. In the same way, we can trace the proper position of the yellow; we want none in the red, gradually increasing quantity in the orange, full intensity in the yellow, and decreasing through the green, till in the pure blue there must be none. This can be shown by another diagram. In the case of the blue, we want none in the red, none in the orange, none in the yellow, but commencing with the green, through blue, into the violet.

Probably, as you all know, these results are obtained in a printing press, and, to make it quite plain, we will assume that we are going to use the ordinary process block for typographic printing. These blocks are made on zinc or copper. When we use a sheet of copper coated with some sensitive compound and expose the same under a negative, we have the coating under the bare places of the negative rendered insoluble; and the result, if such plate is etched, is that the parts not etched stand up in relief, and take the ink from a roller and again transfer it to paper.

It is obvious, therefore, that it is those parts of the negative which are bare glass, or the shadows, which give us the printing surface. So that if we want to print in red, all the red in the picture must be represented in the negative by bare glass. In exactly the same way we find that to make the printing surface for our yellow ink, all the yellow in the picture must be represented by bare glass, and for the blue ink, the blue in the picture must be bare glass in the negative.

To obtain such negatives, it is necessary to stop out or absorb the red during one exposure, and to absorb the yellow for a second exposure, and the blue for the third exposure. This is done by using screens or light filters, which may be either solutions of aniline or other colouring matters, or collodion or gelatin stained with the colours and spread on glass.

The light filter to suppress the red must be green; that to suppress the yellow, a violet; and that to suppress the blue, an orange. It is, I think, unnecessary for me to state the particular dyes which I use; there are so many which can be used, that anyone can adjust the screen by the aid of a photo-spectroscope.

The sensitive salts of silver as used in ordinary photographic plates do not see colours the same way as we do. To the human eye the most luminous part of the spectrum is undoubtedly that about D in the yellow, whilst the particular region of the spectrum which acts most strongly on the bromide and iodide of silver, which are the salts usually employed, is that lying between F $\frac{1}{2}$ G and H. I show you here a spectrogram on an ordinary plate, in which you will see that with an hour's exposure to diffused sky light the action has extended only from H to F. On the screen also is another spectrogram on the same make of plate, exposed for precisely the same time, under as nearly as possible the same conditions, in which you see the action has extended right up to D. In the second case the plate had been rendered colour-sensitive, as we call it, by being

bathed in an aqueous solution of one of the eosine group of colouring matters. This first plate would, if used to photograph an object with bright yellow and dark blue in it, reproduce the yellow as black and the blue as nearly white, whereas the second plate would reproduce the colours more nearly in their visual values. This colour-sensitising of the plates is an extremely important point in three-colour printing, as without it it would be almost impossible to do anything at all.

It is an extremely nice little point in photo-chemistry, as to the precise nature of the combination between the dyes used for colour-sensitising and the silver salts. Some authorities consider that the resultant compound is more of the nature of a lake, whereas others equally as competent consider that a true chemical compound is formed. This, however, I need not enter into.

Briefly summing up the necessary operations as to the production of the prints by this three-colour or indirect method, we can put the whole of the information in tabular form, thus:—

Light Filter.	Plate.	Printing Ink.
Red. Green. Violet.	Red and yellow sensitive. Yellow and blue sensitive. Red and blue sensitive.	Blue. Red. Yellow.

There are, of course, several very important minor points, such as the use of a lens which will give images through the light filters all of the same size; secondly, the nice adjustment of the exposures so as to obtain true tone values of the colours, but these possibly belong more to the fine technicalities of the subject.

Having obtained our negatives, we may use one of three methods for producing the prints: photo-lithography, colotype, or typography. The principle of photo-lithography is that a lithographic stone is coated with some sensitive compound, generally asphalt, exposed to light under a negative, and then developed. The action of light upon asphalt is to render it insoluble in the ordinary solvents of bitumen, such as turpentine; the result is that where the light acts on the asphalt it is not only rendered insoluble, but, as recent researches have shown, it actually enters into some sort of chemical combination with the stone, which is mainly composed of calcium carbonate; and therefore a plate exposed under a negative and treated with turpentine will give us an image which protects the surface of the stone from any etching fluid, such as gum and gallic acid, and the image will repel water, but take up any greasy substance like printing ink. It is obvious, therefore, we can obtain impressions from such an image in any colour.

A colotype plate is obtained by coating a sheet of plate glass with a mixture of bichromate of potassium and gelatin, drying at a fairly high temperature, and exposing under a negative. Where the light acts the gelatin becomes insoluble, and there it will not absorb water. The plate is then thoroughly washed to free it from the bichromate salts, allowed to dry, and again damped, and then rolled up with a roller charged with a greasy ink, which will only take on those parts of the gelatin affected by light. It is thus possible from such a plate to also obtain impressions in any colour.

Typography is the process which is most used at the present time, and it is possibly so used because the results can be obtained in an ordinary printing press. To prepare a block, as it is called, we have first to make a suitable negative by breaking up the half tones into dots of various sizes by using sheets of glass ruled with very fine parallel lines, from 80 to 200 to the inch. Through this negative we print on to asphalt or bichromated gelatin spread upon zinc or copper, and after development the metal is etched away by acid or ferric chloride solution where the light did not act. To make this quite clear, I will ask you to imagine the block to be a piece of cloth, into which we stick innumerable pins, so close together that practically no cloth can be seen. If now we take some of the pins out so as to leave a pattern, and pass a roller charged with a greasy ink over the surface, it is obvious that only the tops

of the pins will take the ink, and if we press a piece of paper on to these, the ink will be taken up by the paper; and if the pins are further apart in one place than another, there will be less ink transferred to the paper, and we shall thus get a representation of light and shade. This is exactly what we do with our block by means of the etching fluid: we take out the metal according to a pattern which has been drawn by light, and leave more or less isolated points which take the ink and transfer it to the paper.

From our three negatives we prepare, then, three printing surfaces, and an impression in yellow is printed first, then on top of this one in red, and finally one in blue, with the result that we obtain a more or less faithful reproduction in colour of the original object.

There are certain requirements which must be fulfilled by the inks: they must be transparent, or else the top printing would not allow the underneath ones to show through; they must be absolutely pure red, pure yellow, and pure blue, and I think I am right in stating that it was only by the aid of Mr. J. W. Lovibond and his tintometer that this was attained; and, thirdly, they must have all the same visual intensity, or else one ink or colour would preponderate in the finished result.

For the indirect method, by using coloured lights instead of pigments, very much the same considerations apply as I have just stated, only of course in this case we use ordinary transparencies on glass which have in themselves absolutely no colour, the silver image merely stopping the light from passing on to the screen. I do not think it is necessary for me to enter in detail into the method of working, but the difference will be most strikingly shown by tabulating the data as we did for printing, thus:—

Light Filter.	Plate.	Projection Colour.
Red. Green. Violet.	Red Sensitive. Green Sensitive. Violet Sensitive.	Red. Green. Violet.

For printing we want two colours to act and one to be transparent in each negative, whereas in projection we want one colour to act and two to be transparent. The results thus obtained may be projected on to a screen by means of lanterns or viewed in an instrument such as you see on the screen.

Instead of utilising glass transparencies, we may from our three negatives prepare three films by exposing bichromated gelatin under them, which would, of course, be rendered insoluble where the light acted, and we should thus obtain on development with hot water—which is, of course, merely the dissolving away of the still soluble gelatin—an image composed of varying thicknesses of gelatin, and these films, if soaked in solutions of various dyes, one red, one yellow, and one blue, would give us when superimposed a faithful reproduction of the original. This method was used by Cros and Ducois du Haumon about 1867, and was revived by Mr. F. E. Ives, of Philadelphia, in 1888. Yet within the last two years an exactly similar process was patented in England and attempts were made to sell the patent for 20,000*l.*, whether the vendors were finally successful I do not know, but in one case at least I was able to prevent a large firm from parting with their money. I might add that the field of reproducing objects in colours has been so well worked that any process now offered for sale as new must be looked upon with considerable suspicion.

There is yet another process which is founded upon the theory of the three primary colour sensations, which was discovered by Dr. Joly of Dublin. In this process he takes advantage of the fact that when fine lines are ruled very close together in different colours the result will be a mixture resulting from the admixture of the coloured lights transmitted by the various colours. He used red, green, and violet pigments ruled on glass in fine lines varying from 300 to 400 per inch, through such a screen one negative is taken and from this negative is made a transparency, which will, of course, be divided up into parallel lines of deposit, according to the light transmitted by the coloured

pigments, and on the top of the transparency he places another sheet of glass, also ruled with the pigments necessary to excite the three primary sensations, and when such a positive is projected on to a lantern screen, or viewed at the distance of normal vision, the result is the production of colour. I see now that instead of using pigments Dr. Joly proposes to use silk fibres dyed to the required shade.

It has been stated that MacDonough in America anticipated Joly by using irregular dots of colours instead of parallel lines, and this process has now been applied to the production of printing surfaces, but till I see some results I am unwilling to do more than record the fact as stated, because there seem to me to be some big difficulties in the way of successful results.

The rationale of these two processes is, of course, that instead of using three separate screens and making three exposures the light filters are placed on one glass and only one negative is used.

DISCUSSION.

The CHAIRMAN, in inviting discussion, said that each of the papers read that evening had an important position on the borderland of chemistry, and as there were several members present having an intimate knowledge of the subjects dealt with, he hoped they would throw further light upon them.

Mr. J. W. LOVIBOND had listened with the greatest attention to the very interesting address. The part which appealed to him most was that which dealt with the loss of the trichromatic printing industry to this country, and its success in America and on the Continent, and he agreed with Mr. Wall that the lack of technical training here was in a large measure responsible for this loss. Speaking as one who had worked at and studied that special subject for many years, he had come to the conclusion that the teaching of the Young-Helmholtz theory as a final explanation of colour phenomena had barred the way to progress in this country; as he frequently found scientific men who had adopted this theory, and were reluctant to accept evidence on colour questions unless that evidence chimed in with it. It was extremely interesting to find in practice that the three colours red, yellow, and blue, provided they were pure, were all that was necessary to give the most natural reproduction of colours. He was astonished at some of the beautiful greens that had been produced on some of the plates shown, as that colour had usually been the weak point in such processes. Another bar to progress had been that they had not dealt with colours as having different degrees of intensity. For instance, to produce a pure orange, red and yellow of equal intensity must be used; but yellow was seldom found with more than 16 units, while red frequently had 32 to 40 units. It must therefore be fully realised that to get a pure orange a double quantity of yellow must be used in order to get a proper reaction for transmitting the orange rays purely. He understood the author to say that all three colours must be transparent, but he was not sure whether the yellow might not be opaque and put on first, but, if so, greater care must be taken with the stippling. Two transparent colours might lie over yellow. He looked upon a paper of the character of that just read as one which would do something to redeem our technical men from the slur of our having to go abroad for such work as had just been passed round.

Mr. F. W. T. KROHN wished to know whether it was possible by the Lippmann process to obtain reproductions by taking fresh negatives of the original negative by reflected light, obtaining the colours used in successive negatives from the original one. He had frequently heard it stated that out of 20 prints obtained by the three-colour process, only one would be exactly true to the original, owing to the difficulty of superimposing the necessary quantities of pigments. He would like to know whether these difficulties had been overcome, and whether it was possible to get a larger number of correct prints.

Mr. J. D. GEDDES, referring to Mr. Krohn's remark, said that some of the worst specimens shown he had had a hand in preparing. If Mr. Wall would allow him to answer Mr. Krohn's question, he would say that in the collotype

process it had been his experience that even prints could not be obtained in a large quantity because the collotype plate gave up its ink according to the moisture and ink-holding power of the gelatin employed. In printing red, blue, and yellow, each print varied from its predecessor in taking up ink, and so the balance would be wrong in one or other colour. That had, to a large extent, been got over by using blocks, and specimens obtained in that way were much more even. How far they might have to go before the exactitude of fine chromo-lithography was reached he could not say, but they were on the high road to producing a printing process which would overcome the difficulties of photographic lithography, and at a lower cost when only a small quantity was required.

Mr. W. BRAMM wished to know whether the coloured photographs shown in shop windows were produced by this process.

Mr. P. McEWAN asked whether Mr. Wall could give any information as to the permanency of the prints. One naturally supposed that the red was produced from vermilion, and that the yellow was chromate of lead. Had experiments been made to determine whether there would be a gradual blackening of the yellow in the course of time? He would like to mention that French printers had also done excellent work in the same direction, and it would be a pity if the meeting closed without reference to it.

Mr. J. F. FÜRST wished to say on behalf of Messrs. Lumière that they had lent their original coloured photographs so often, and had had so many narrow escapes of losing them in transit, that they had at last decided not to do so any more.

Mr. E. J. WALL, in reply, said that with regard to Mr. Lovibond's remarks as to the Young-Helmholtz theory having barred progress, it might be so, but it was a very convenient theory, and that was the only reason why he had referred to it. Having been brought up in the old school, he had, to some extent, a lingering belief in the old theories; at the same time, Mr. Lovibond was doing his best to convert him to the new. With regard to the necessity of having the three colours absolutely pure, he ought to state that it was not until Mr. Lovibond came to the aid of the printing-ink maker that it was possible to obtain these colours pure. He had referred to the reproduction of greens as being the weak point hitherto, and that that had something to do with the purity of the inks. That was not so. When a plate was sensitised for colours, green was the most difficult colour to deal with; there was always found a want of sensitiveness to the green of the spectrum. An ordinary plate would give a closed band of ordinary deposit running up to F unless exposed for an abnormal time and a deep screen were used. If a plate was sensitised with one of the cosine dyes (and there were only about three dyes that could be used to sensitise the green), a closed band from H to F would be obtained, and then there was very little sensitiveness until about D $\frac{1}{2}$ E was reached, so that a bad reproduction of the green was always obtained, because until within the last few months it was not known how to sensitise the bromide of silver for the green in the spectrum. When a plate was sensitised for the yellow or green in the ordinary way it really showed a want of sensitiveness in the green. That was always overcome in the three-colour process by making an allowance and cutting down the blue rays so as to give the green time to act. He had said that an ordinary plate was not sensitive to green. As a matter of fact it was possible to take a picture on ordinary bromide of silver by the red rays, it being a question of length of exposure. Mr. Lovibond had referred to the necessity of all the three colours being transparent. Theoretically that was true. He said he did not think it was necessary to have the yellow transparent. The reason why yellow was printed first was because it was not quite transparent. It was exceedingly difficult to get a yellow printing ink which was at the same time permanent and transparent. If the inks were absolutely transparent it would not matter in what order they were printed. Another member asked whether it was possible to obtain a reproduction of Lippmann's photographs without a second sitting, that is to say, by re-photographing the original. That question had occurred to him, but he had been told that it was not possible to do

so. Personally he did not quite see why it should not be, and he hoped at some future time to test that point practically. The same speaker also said that he had been told that it was only possible to get about one print out of 20 correct. As Mr. Geddes had stated, only about one in 30 was satisfactory, because the plate did not take the ink equally. With his native modesty, Mr. Geddes referred to the worst of the specimens shown as his, but he was one of the first to produce three-colour plates in England, and it would be some time before his three-colour printing would be beaten. He (the author) thought with Mr. Geddes that in photo-lithography we had the process of the future, but it wanted working up. He was still engaged in that pursuit, and he hoped at some future time to show how to turn out the three-colour prints so that they were perfectly even, and still better than the present ones. With regard to the question as to whether the prints shown in the shop windows were photographs in natural colours, he presumed the speaker referred to the Photochrome Zürich Company's specimens. They were not produced by pure photography. One negative only was taken, and from that five prints were made and were coloured by hand, and then those were transferred to stone; the greater part was handwork. There were several other processes in which handwork was used to a large extent, but he confined himself to the photographic reproduction of colours without any handwork, because it was extremely difficult for artists to know exactly how much colour must be stopped out to reproduce the original. He was perfectly convinced that he could reproduce the colours, and he did not see why he should need an artist. Handwork was uncertain and expensive, and the photographic process was the only process of the future. With regard to the permanence of the prints, it depended entirely on the pigments used for the inks. The red was not produced from vermilion, but from madder; the yellow was not from chromium, but from zinc. The blue he was not at liberty to mention, because he discovered its origin accidentally. Some of the specimens were printed in inks that were not permanent; the others were permanent. He had had prints with these latter inks exposed to daylight and not under glass, where the sun could reach them, for seven months, and there was no sign of fading at all. It was, of course, an important point in the manufacture of inks that they should not fade. With regard to the French work, he had to confess that he was ignorant of any that had been produced by the three-colour process without handwork. Most that he had seen depended to a great extent on artist's work, either on the negatives or on the plates. He could easily understand Messrs. Lumière's hesitation in sending specimens; for they were valuable, and to have them lost would be a very great trouble. He believed they prepared them for the love of the thing, and they looked upon them as their children.

Meeting held Monday, June 1st, 1896.

MR. B. E. R. NEWLANDS IN THE CHAIR.

JAPANESE METALLURGY.—PART I.—GOLD AND SILVER AND THEIR ALLOYS.

BY W. GOWLAND, A.R.S.M., F.I.C., F.C.S.

Late of the Imperial Japanese Mint.

GOLD is called by native writers the "King of the Five Metals" because say they it never rusts and may be melted many times without appreciable loss of weight. Following the teachings of the old Chinese philosophers, it was believed that under special conditions, other metals could be converted into gold, but this transmutation could not be effected in a laboratory, as a space of not less than 200 years was required for its completion even under the influence of celestial agencies. Probably, in consequence of this belief in the all important influence of time, alchemy does not appear to have been practised in Japan, and much as the acquisition of gold was sought after, no records of any attempts to transmute a baser into the more noble metal have been handed down by tradition.

The source of the gold in Japan, as in all countries in early times, was the sands of rivers, from which the metal was obtained by a series of simple washing processes. At the present day some is still similarly obtained, and sometimes from sands containing such small quantities that western washing processes fail to compete successfully with the primitive methods of the Japanese gold washer.

In treating these sands, the coarser particles and pebbles were first separated by a kind of hand-jigging in tubs of water with a series of circular baskets of bamboo about 2 ft. in diameter and 6 ins. deep of varying fineness.

The "fines" were then washed on vanning dishes of wood about 20 ins. in diameter and 2 ins. in depth.

Sands containing not more than 180 grains of gold per ton can be thus washed with profit, and a skilful washer will detect the gold in material containing only 30 grains per ton.

The old gold washers are said to have received no wages, sufficient gold dust adhered to their garments, and it is naively added, that sometimes even a nugget became accidentally attached, and this was sufficient to recompense them for their labours.

When the sands and gravels were unusually poor in gold, they were treated by a method of washing in short sluices in the nearest stream. These sluices were either made in the stream itself, or trenches were dug parallel with it and the water of the stream was directed through them in a current of considerable force. The washing portion of each sluice usually measured about 20 to 25 ft. long by 2 to 3 ft. broad.

The gravel was first well washed at the upper end of the sluice and the larger pieces were picked out. After this rough washing, coarsely woven straw mats were placed lower down, and the gravel was then shovelled gradually upon them in such a manner that it was carried over their surfaces by the current. During this operation the heavy

magnetic iron sand and the gold were caught between the fibres of the mats. The mats were then taken up and the concentrated material which had been retained by them was washed on vanning dishes. This method can be strongly recommended for prospecting poor auriferous gravels as the appliances required are so simple. It was tested in Yezo on a large scale by Prof. H. S. Monroe, an American mining engineer, and from his experiments he concluded that where there was an abundant supply of water, and with the cheap labour available in Japan, gravels yielding only 6 cents worth of gold per cubic yard could be washed with a small profit.

In later times mineral veins bearing gold were discovered and the precious metal was separated from them by washing after the ores had been reduced to powder. The appliances used for crushing were of the simplest kind. The large pieces of rock were broken up with hand hammers to the size of large walnuts, and then reduced to coarse powder by means of a curious form of stamp which was worked with the foot.

The stamp consists of a horizontal beam of wood with an axle set near one end, resting on bearings on an upright block. To one end of this beam the stamp head shod with iron is fixed, and also several blocks of stone to increase the force of the blow. The other end is prolonged by fitting to it a plank of wood and on each side of this is an inclined platform. In working the stamp the workman steps from this platform upon the plank at the end of the horizontal beam with one foot, resting his whole weight upon it and thus raising the stamp head, he then quickly steps back to the platform and the stamp head descends with great force into the mortar. The mortar is generally cut out of a large block of stone.

After the ore was thus roughly ground it was treated in the manner shown in Fig. 1, which is copied from an old manuscript of last century.

Fig. 1.

GRINDING AND WASHING GOLD ORE.

The ore was ground with water to a fine pulp in a horizontal mill resembling a flour mill. When rich it was washed at once in "dolly" tubs and the "concentrates" on vanning dishes, otherwise it was taken to the cistern shown on the left of the diagram, from which it was allowed to flow on to straw mats, thence down the inclined troughs on the bottom of which long sheets of cotton cloth were laid.

The particles of gold were caught on the rough surface of the cloth and the earthy material was carried away by the water. After a time the cloths were washed in tubs of water and the gold separated. But little gold has been obtained during recent times by the processes I have just described, and the chief sources of the metal have been silver ores, in which it always occurs, sometimes only to

the extent of a few pennyweights or even less per ton, but occasionally reaching as much as 3 or 4 ozs. or more.

Japanese gold dust is always in the form of very small flakes, the largest of which rarely exceeds 8 grains in weight. The composition of five typical specimens which I examined is given in the following table:—

TABLE I.—COMPOSITION OF JAPANESE GOLD DUST.

	From the Province of Iyo.			From the Province of Bizen.	
	1	2	3	4	5
Gold.....	90.52	90.38	90.35	87.52	88.62
Silver.....	9.25	9.40	9.10	11.05	10.30
Iridium.....	present

It differs from the gold dust of Korea in its higher proportion of gold and also in being sometimes associated with iridosmine.

I first discovered iridium in Japanese gold dust in a sample from Iyo in 1884, but it had been a source of trouble in old times to the makers of gold ornaments for the sword, owing to its dissemination through the metal in crystalline particles as iridosmine which resisted the action of their steel chisels. Since then my friend and former assistant Mr. Koga, now the chief assayer of the Imperial Mint, has found it in some of the coins of 1716 A.D.

Uses.—Gold, although found in many localities in Japan, was never abundant, and the glowing accounts of the early voyagers respecting the wonderful richness of the country in gold have no foundation in fact. Doubtless they had their origin in the erroneous assumption that the ornamental plates and appendages which were seen to adorn the principal temples and even many ordinary dwellings were of solid gold, whereas they are only gilded copper. But the sumptuary laws which were enacted from time to time prove that gold was always a precious metal to be used sparingly.

To 1875, before which date the mineral statistics of Japan are not very trustworthy, the total quantity of gold produced in the year was only 5,599 ozs.; but during the 18 years which followed, this amount has been greatly exceeded owing to the extensive introduction of European processes, and in 1893, the date of the last returns, the annual production had reached 23,675 ozs.

One of the earliest uses of gold was as a coating for other metals to protect them from oxidation and for purposes of display. Thus in the early centuries of our era, we find it thus employed for coating bronze and copper rings and other objects for personal adornment, and iron horse-bits, and ornamental appendages which were attached to the trappings of horses.

In later times, especially after the introduction and establishment of Buddhism in the 6th and 7th centuries, gold comes into use on a more extensive scale, its chief application being for the gilding of bronze and wooden images of Buddhist Divinities and of copper vessels and objects for ceremonial purposes, and plaques and studs for the decoration of shrines. Considerable quantities of gold were needed for their purposes as the leaves of the metal employed were of much greater thickness than those now used in Europe.

The method by which the surface of copper and bronze were coated with gold, even in very remote times, depends on the use of mercury, and as no ores of mercury had then been found in Japan there is but little doubt that the process had been introduced from China where it was known some centuries B.C.

The process is a very simple one. The object of copper or bronze to be gilded was immersed in vinegar made from the juice of anripe plums until a clean metallic surface was obtained. It was then washed with water and dried over a brazier, and mercury was applied to it whilst it was still warm. When the surface had thus been amalgamated, the gold was laid upon it in the form of leaves. A stronger

heat was then applied, the mercury was volatilised, and the gold left perfectly adherent.

Even up to recent times, objects of solid gold, excepting those of very small size, were seldom made. Gold plate was unknown, and in the palaces of the wealthiest military nobles, the only vessels of the precious metal, either for use or ornament, were a few wine cups and diminutive kettles for heating water or wine and these were by no means common.

Two gigantic fishes about 9 ft. in height which adorn the roof of the chief tower of Nagoya Castle are said to be of solid gold; but some years ago I had an opportunity of examining one of them and found that like many objects of historical interest they are not what tradition represents them to be but are only of copper coated with gold.

Gold jewellery—in our acceptance of the term—was worn but sparingly, so that the use of gold in the art of the metal worker was practically confined to the decoration of the furniture, of the sword, and the fittings of the pipe and tobacco pouch. The latter, and also the small ornaments “menuki” attached to the sides of the grip of the sword, were often made of gold of great purity. One specimen which I analysed contained, gold, 98.1 per cent.; silver, 1.4 per cent.; copper and lead, 0.5 per cent.

For other objects, alloys of gold with silver, containing much less gold and approximating in composition to the mint coins were generally employed.

In the 17th and 18th centuries there were no less than three different standards of fineness for the gold coins issued by the mint, viz.:—

	Per Cent.	Per Cent.	Per Cent.
Gold.....	86.0	67.0	54.0
Silver.....	13.0	28.0	44.0

and gold articles of this period vary similarly.

But in the 19th century, before the establishment of the Imperial Mint on foreign principles there was a further debasement of the gold standard, still poorer alloys were issued, in which the proportion of gold fell to 35 per cent., 20 per cent., and even to 12.3 per cent.; the last being the poorest alloy which by any pretence might be called gold. Yet from the peculiar treatment to which they were subjected—which I will describe later—they are undistinguishable from pure gold in external appearance.

The 16th century was chiefly remarkable in the annals of gold for the first coinage of the metal by the Government of Japan. In earlier times bags and quills containing definite quantities of gold dust fulfilled the purposes of a gold currency, and their use survived even up to the present century.

Japanese Gold Coins.—The first Government mint was established about 1569 A.D.

One of the first issues of this mint was called an ōban. It is a very large coin in the form of an oval plate, measuring 7 ins. in length and about 4 ins. in breadth, its average weight being 5.3 troy ounces, and its average composition—

	Per Cent.
Gold	73.84
Silver	24.00

Its actual value in our money is about 18l. 8s. The inscription on the obverse is written in Chinese ink, the upper portion indicates its value, viz., 10 ryō, and the lower is the monogram of the master of the mint, made especially complicated to prevent counterfeiting. The reverse is an illustration of the mode of decorating the surface of metals termed “tsuchime” or “hammer face,” in which long shallow oval indentations produced by a hammer of peculiar form are arranged in symmetrical order.

Of the smaller coins of the same date, which were used in making payments in ordinary commercial transactions, the largest was the “koban” or one ryō piece, the value of which is one-tenth of the “ōban.” It is about 2½ ins. in length. There was also the “nibuban” or half koban.

The “ōban” of the Keichō period (about 1601 A.D.) is composed of gold 67.43 per cent., silver 28.50 per cent.,

and its value is about 16 guineas. It is chiefly interesting to us from the curious texture of its reverse side, which is called "ishime" or "stone face" as it represents the structure of the surface of stone, and was produced in early times by hammering the metal on a stone anvil, but later by the use of punches of various forms.

The "Goryōban," coined in 1843 A.D., is $3\frac{1}{2}$ ins. long, weighs 1.08 troy ounce, and is composed of gold 84.2 per cent., silver 15.4 per cent. It is equivalent in value to five koban or half an ōban, and is probably the most beautiful of all the old Japanese coins. Oblong and square pieces of smaller denominations, viz., the half, eighth, and sixteenth of a koban, were also made.

In addition to the production of coins it was also a function of the mint to prepare for the Government from time to time large bars of gold called "Homa," which were to be kept in the Treasury as a reserve against war, famine, or other calamities. An inscription on the upper surface of one of these bars prohibited its use for any but extraordinary expenditure. On another we find "Peace and treasure endure together," meaning that "a reserve against war is a guarantee of peace."

Many other examples of the old coins might be mentioned, but they would scarcely interest you, as they all closely resemble the above. They are, however, well illustrated in the plates exhibited, and in the small collection of repre-

Fig. 2.

SEPARATION OF AU FROM AG.

sentative specimens on the table. The similarity which the various coinages of the Japanese bear to one another is a feature which we would hardly expect from such an artistic people; the designs are singularly deficient in artistic merit, and exhibit no traces of that fertility of conception which distinguishes all their other works in metal.

But the methods pursued in the old mints for their production are of special interest, as they are for the most part identical with those practised by all workers in gold and silver, almost up to the present day, and many are unique in the art of working metals. The operations are all illustrated in minute detail in the manuscript rolls exhibited, a few of the most important only I will now describe briefly.

On the receipt of gold bullion at the mint it was necessary to determine the actual proportion of gold present in it. The assay was performed by means of the "touchstone," and a series of small bars or plates of gold alloyed

with definite proportions of silver according to a decimal scale. These trial plates were prepared by the Government, and were used not only in the mint but all goldsmiths' wares are said to have been compared with them, even in mediæval times, in order to determine their fineness.

The "touchstone" is a small flat piece of black siliceous shale. The gold to be assayed was rubbed on the smooth surface of the stone, and the colour of the streaks produced was compared with that of similar streaks made near them by rubbing on it one or more of the definite alloys. No acids or chemicals were used. This method is still practised by craftsmen working in gold, and by it a skilful expert will obtain results not differing in extreme cases more than 10 parts in a 1,000 from assays made by our methods.

When the gold was found to contain an undue proportion of silver it was submitted to a curious process for the separation of the latter metal. (Figs. 2 and 3.)

Fig. 3.

SEPARATION OF Au FROM Ag.

It was first reduced to a coarse powder by heating it to near its melting point and then rubbing it on an iron plate with a stone or iron rubber.

The coarsely powdered gold was then mixed with common salt and a certain proportion of clay and piled up in the form of a cone on an earthen dish. The whole was then placed in a furnace containing charcoal as fuel, and was kept at a red heat for at least 12 hours, by which means the silver was converted into chloride. The dish with its contents was then removed, washed with hot brine and water, the silver chloride was dissolved and the gold left in a purified state.

The gold was then melted and assayed by the touchstone, and if too much silver was still present it was again treated as above.

(This method was in universal use in Japan up to the establishment of the Imperial Mint in 1870.)

If the gold was found to be sufficiently pure it was melted with the proper proportion of silver required for the coinage alloy and cast into bars in iron moulds.

The melting room of the old mint contained furnaces of a very simple kind—mere cavities in the ground, lined with fireclay, to which a blast is supplied by means of a box bellows. The fuel was charcoal.

The Crucible used consisted of a thin inner cup of hard porcelain enclosed in an outer cover of fireclay, and its construction affords a good example of the ingenuity of Japanese metallurgists in overcoming the difficulties arising from the non-refractory character of their fireclays.

When the gold bars were taken from the moulds they were hammered with sledge hammers into long plates of

suitable thickness for the coins, being annealed when necessary by heating them over a charcoal fire.

The hammered plates were then taken to an assay department where they were tested for copper by a method which is unique in assaying operations.

Here the metal was heated to redness over a charcoal fire and when at the proper temperature was rubbed with a stick of "hinoki" (the wood of the *Chamaecyparis* or *Thuya obtusa*) and then immersed in water. The presence of copper and its approximate amount was determined by the colour and appearance presented by the part to which the stick of wood had been applied. So successful were the old operators in the application of this test that it is rare to find more than 0.25 to 0.35 per cent. copper in the old coins.

If the copper was found to be in excess the plates were subjected to the process of cupellation with lead for its removal. Otherwise, they were now cut up with shears into pieces of the shape and approximate size of the intended coins. After the weights of these had been adjusted, the peculiar texture and markings I have already described were given to their surfaces. The devices and the private marks of the inspectors were now stamped by hand with small iron stamps on each coin. They were then sent to the colouring room.

Owing to the large proportion of silver which, as we have seen, all Japanese gold coinage alloys contained, the coins were still nearly white in colour, and it was necessary to give them a surface of gold.

This was effected, not by any ordinary gilding process, but by dissolving out the silver from the upper layers of the alloy.

Fig. 4.

COLOURING GOLD COINS IN THE MINT (18TH CENTURY).

The coins were first painted with a brush with a mixture composed of iron sulphate, copper sulphate, potassium nitrate, calcined sodium chloride, and resin, made into a paste with water. They were then carefully heated on a grating fitted over a charcoal fire. After this they were immersed in a strong solution of common salt, washed with water, and dried. By this means the silver was dissolved out from the upper layers of the alloy and a surface of pure gold left.

The operations were repeated, if necessary, two or three times for the poorest alloys, until the surface had the colour of fine gold.

These old processes were, with a few trifling modifications, practised by all craftsmen when working in gold.

SILVER (Jap. GIN).

"Gin," or, as it is sometimes called, "shiro-kane," "the white metal," has been in use in the country from an early period.

The first examples we have of its use are bronze and copper rings coated with silver, bands of the metal encircling the scabbards of swords, and beads for personal ornament, several of which I discovered in the chambers of the ancient burial mounds.

From this time until the mediæval period objects of silver are not very common. The cold and sober colour of the metal unfitted it for the gorgeous display aimed at in Buddhist temples and ceremonies, so that it was used but seldom for their religious vessels or altar ornaments. Hence, up to near the beginning of the 16th century specimens of a few coinages and a few sword mounts are the only examples of its use which are in existence. From that time there was a marked extension of its use, especially in the form of its alloys with copper, for the ornamental guards and other furniture of the sword; and in the 18th, but more particularly during the present century, objects rarely made of the metal heretofore, such as kettles, vases,

and ornaments, have been largely produced, many of which are masterpieces of the decorative art of the Japanese workers in metal.

The chief ores from which silver was obtained in Japan until recent times were galena, copper pyrites, and iron pyrites, with which were associated argentite, tetrahedrite, native silver, and pyrrargyrite. A common ore consisted of copper and iron pyrites, galena, and zinc blende, with one or more of the above-mentioned silver minerals, and in which in some mines the copper pyrites predominated, and in others the galena. In the former case the ore was smelted for copper and the silver was concentrated in that metal; in the latter it was smelted as a lead ore, and

Fig. 5.

CUPELLING SILVER LEAD.

the silver was obtained in the lead reduced. Ores of an intermediate character yielded copper which sometimes contained large quantities of lead. Those which contained less than about 20 oz. of silver per ton were concentrated by dressing up to this value, or were mixed with richer material for smelting, and in all cases as much of the zinc blende as possible were separated by hand picking. If they contained only small percentages of lead or copper they were smelted with ores containing larger proportions of these metals.

No wet methods of extraction were known, so that all the silver was obtained by furnace processes.

The silver-bearing ores as they were taken out of the mines contained generally from about 6 to 32 oz. of silver per ton of ore, but occasionally the veins yielded rich pockets of ore, which in one case, at the Handa mine, assayed 2,776 oz. 12 dwt. per ton.

Since 1875, when the annual outturn of silver was only 224,831 oz., the production has increased about tenfold, that of 1893 having been 2,226,717 oz.

There is not a single modern process in the metallurgy of either silver or gold, which is practised in Europe or America, which has not been introduced into the country, especially for the treatment of poor ores, and in future the production of these metals will certainly further increase.

The furnace which was universally used for smelting all ores of whatever kind, I have already described before the Society (this Journal, 1894, 465, Fig. A); when thus employed it was partially covered with a thick semicircular lid of clay.

The process of smelting argentiferous copper ore was conducted as follows:—The furnace was first filled with ignited charcoal, and after the blast from the two box bellows which were placed behind it had been started, a layer of ore was spread over the upper surface of the fuel, then a layer of fresh charcoal, then a layer of ore, and so on, until a conical heap of ore and charcoal was formed about 2 ft. in height with a base of about 3 ft. in diameter. As the charge melted, additional quantities of ore and fuel were added until the furnace cavity was nearly full of molten material, consisting of copper matte containing the silver, and slag. The fire was then raked away and the slag skimmed off from the matte with a skimming tool with a wooden head.

The argentiferous copper matte was then reduced at once to metallic copper by directing a strong blast upon its surface by a steeply inclined twyer, a little charcoal being placed around the sides from time to time to prevent chilling. When the whole of the matte had been reduced, the copper was taken out of the furnace by sprinkling water upon its surface with a straw brush, and lifting out the thin solidified crusts thus formed with an iron bar. In some cases the matte was reduced to metallic copper in a separate furnace.

About $1\frac{1}{2}$ to 2 tons of ore could be thus smelted in one furnace per day.

The silver was separated from the copper by liquidation with lead, a process which I have described in a former paper (*Ibid.* 1894, 463).

When the ores contain an excess of lead and but little copper, the smelting process is precisely the same as the above, excepting that a more moderate blast is used to avoid as far as possible excessive volatilisation of lead. When the charge has all been melted down, the slag skimmed off and a little matte which is always formed removed, the argentiferous lead is laded out into shallow cavities in the floor of the smelting house.

For smelting cupriferous ores the furnace is an excellent one. For lead ores it is not satisfactory. For example:—In smelting a galena in which I found 69 per cent. lead and 125 oz. 8 dwt. of silver per ton of ore, only 40 per cent. of lead was obtained, and there was besides a considerable loss of silver.

The argentiferous lead, whether it is obtained from the liquation of copper or by the direct smelting of ores rich in galena, is cupelled in the furnace shown in Fig. 5.

A bellows is placed at one side and the blast is delivered above the middle of the hearth by a twyer bent at right angles.

The hearth of the furnace is composed of wood ash, from which the soluble salts have been washed out with water. A square box about 3 ft. wide and 3 ft. deep is first fixed in the ground forming the floor of the cupellation room, and in this the wood ash is firmly stamped down, the upper surface of the ash being about level with the surface of the ground. A circular shallow cavity 12–16 ins. in diameter and $2\frac{1}{2}$ ins. deep is then made in the surface of the ash and carefully smoothed. Ignited charcoal is then piled in the cavity and slabs of fireclay incurved at their upper edges are placed around, forming a rudely circular chamber about 18–20 ins. diameter, which is open at the front, but partially closed at the top with a fireclay slab.

The argentiferous lead to be cupelled is now placed on the charcoal, the bellows are started gently, and when the metal has melted and filled the cavity in the hearth, the charcoal is pushed away and piled around the molten lead. The lead being thus fully exposed to the action of the blast is gradually oxidised, the lead oxide formed is absorbed by the hearth, and any scorific of infusible oxides are removed by means of a small skimmer. More argentiferous lead is added from time to time if required, and when all has been oxidised, a cake of silver remains on the hearth. From 70 to 90 lb. of lead can be thus cupelled in about three hours, with a consumption of about one-fourth its weight of charcoal.

The silver thus obtained is generally very impure from the presence of copper, bismuth, arsenic, &c., and is hence again cupelled with pure lead in another but similar furnace.

The native metallurgists were very skilful in conducting this process, and seem to have had no difficulty in producing silver of considerable purity by means of it. I have assayed the silver thus treated very often, and the most impure specimen I have ever found contained 98.5 per cent. and the purest 99.7 per cent. silver. Its average composition deduced from the assays of 555 samples was 99.3 per cent. silver. Even in very ancient times, during the period of the dolmen builders, the Japanese seem to have been skilled in the metallurgy of this metal, as the silver beads of that date contain but very small proportions of lead and copper.

In making silver objects, and also for the older coinages, the metal was sometimes used in this pure form, but generally small quantities of copper were added, not for the purpose of debasing it, but to increase its hardness, and also in order to obtain castings free from vesicular cavities—a matter of some difficulty with pure silver. The composition of some of the older silver coins, sword mounts, &c. is given in the following table:—

“OLD” SILVER COINS, SWORD MOUNTS, &c.

Description.	Silver.		Copper with a little Lead.	Analyst.
	Per Cent.	Per Cent.		
Silver coin “Nishu,” 1773 A.D.	97.81	0.13	2.06	Koga.

Poor alloys are sometimes found, although never in silver work by good artists, and they may contain not more than 50 per cent. of silver, and occasionally very much less. But these are generally special alloys, bearing the generic name “shibuichi,” which are not used as or considered to be silver, but are employed by art workers for producing special decorative effects of colour, owing to the beautiful grey patina which they may be made to assume.

Unfortunately they have also been used for the sake of gain, in the production of what may be termed counterfeit silver articles, by subjecting them to a series of processes which will be described subsequently.

The methods and processes practised by the Japanese in the working of silver are analogous to those which I have described under gold. Its value was determined by means of the touchstone and trial plates or needles of definite alloys of silver and copper—a method not so accurate as for gold, although a skilful expert will ascertain the proportions of the metal present in a rich alloy within $1\frac{1}{2}$ to 2 per cent.

In the old mints and silver refineries, the metal was melted in a furnace consisting simply of a hemispherical cavity in the floor of the melting room, lined with refractory clay mixed with charcoal. The bellows were started, and when the silver was completely melted and the necessary proportion of copper had been added, the fire was raked off, the molten metal stirred well with a stick of pine wood, and ladled into iron moulds with an iron ladle.

It was never cast in ornamental forms, but always in small cakes or bars, which were fashioned solely with the hammer and chisel.

Crucibles were rarely used excepting for melting very small quantities in the workshop of the craftsman, and then the metal was poured into moulds of stone (a volcanic tuff), clay, or loam.

When bars of debased silver, *i.e.*, silver containing undue proportions of copper, were cast, a practice which unfortunately was not seldom followed, even in the old mints—especially for commercial bars—when the military rulers of the country were in need of money, a special mode of procedure was adopted. The silver was then poured into canvas moulds, which were set in troughs of hot water, the reason for this being, that the alloy contained so much copper that, if cast in the ordinary way, the bars would

be coated with a black layer of oxide from the action of oxygen of the air on the copper, and this was difficult to remove. By placing the moulds under water this oxidation was prevented, and castings with a clean metallic surface were obtained. Those bars were, however, of a coppery hue, and this required removal. They were therefore heated to redness over a charcoal fire, and then plunged into vinegar—made from the juice of unripe plums—containing common salt in solution. After digestion in this for some hours they were washed with water and then boiled in plum-vinegar without salt for one or more hours, when they were washed with boiling water and dried. By these operations the copper in the alloy was removed from the surface layers and a coating of pure silver left.

These mint bars sometimes contained only 13 per cent. of silver. Yet so successful were the Japanese in carrying out this method of treatment that these low alloys often cannot be distinguished from purer silver without special examination.

The operation of digestion or boiling in plum-vinegar was also practised for all coins and other objects, even when they consisted of silver of considerable purity. But the chief works by which the old metal workers of Japan have made themselves famous, not only in technology but in art, were not executed in either gold or silver, but in their alloys.

Of these the most important are “shakudo” and “shibuichi,” the former being an alloy of gold with excess of copper, and the latter of silver with an excess of the same metal.

Shakudo.—Shakudo is of a dark copper colour, differing but little from ordinary bronze, and its value as a decorative alloy is entirely dependent on the beautiful black patina which may be produced on its surface by suitable treatment.

Its composition is given in the following table of analyses:—

ANALYSES OF THE ALLOY “SHAKUDO.”

—	Gold.	Silver.	Copper.	Lead.	Iron.	Arsenic.	Total.	Analyst.
1	4.16	0.08	95.77	100.01	Kalischer.
2	3.73	1.55	94.50	0.11	Trace	Trace	99.89	Gowland.
3	2.67	2.06	94.90	0.11	99.74	..
4	2.45	1.24	96.00	0.06	99.75	..
5	1.52	2.01	96.10	0.08	99.71	..
6	1.00	1.37	97.40	0.07	99.84	..
7	0.49	0.29	99.04	99.82	Atkinson.

The presence of not less than 3 per cent. of gold is absolutely essential to obtain the finest black surface with violet sheen, which is seen in the choicest specimens of the alloy.

There are, however, according to the classification of the Japanese craftsmen, not less than 15 grades of shakudo; the lowest, which is known as “chu sho,” contains only traces of gold. The shakudo of the Satsuma craftsmen is generally considered to be the richest and most valuable, although that used by Ishiguro Masatsune, of Tōkyō, and by one or two others, approaches and often equals the former in excellence.

The alloy has been long known to the Japanese, but there are no records of its first use, and the date of its origin cannot be even approximately determined. Perhaps the least doubtful of the earliest specimens known to me are the mounts of the sword of Ashikaga Takauji, who held the position of shōgun from 1335 to 1357, which is preserved in the temple of Itsukushima.

There may be earlier examples, but it was certainly not known in the 9th century.

The oldest specimen of Buddhist art metal work in the decoration of which shakudo appears, so far as I have been able to trace, is a reliquary containing fragments of the bones of St. Nichiren in the famous temple of Minobu (date 1580).

In many temples there are statues of divinities and saints which are said to be composed of this alloy, but those I have had an opportunity of examining were all of ordinary copper-tin-lead bronze.

In the 17th century it was extensively employed, but the finest examples of its use as a decorative alloy are found in

the guards and other furniture of the sword of last century and the first half of the present.

The addition of gold to bronze in order to obtain a black patina has been long known to the Chinese; it is hence possible the Japanese may have learnt from them this peculiar property of gold; but the pure alloy of copper and gold, the true shakudo, is essentially Japanese, and is unapproached in the beauty and richness of its patina by any alloy of the Chinese, either of old or recent times. Its deep, rich tones of black and the splendid polish which it is capable of receiving, render it alike a perfect ground for inlaid designs of gold, silver, and copper, and for being similarly inlaid in them.

This alloy, too, possesses physical properties which are of extreme importance to the worker in metals, and enables him to manipulate and fashion it as he desires. It can be cast into any form, can be hammered into sheets and drawn into wire; no large castings have, however, been made of it.

The method by which the black patina is produced is as follows:—The object is first boiled in a lye prepared by lixiviating wood ashes, after which it is carefully polished, if necessary, with charcoal powder. It is then immersed in plum-vinegar containing common salt in solution, and after being washed with a weak lye is placed in a tub of water to remove all traces of alkali. After this treatment it is digested in a boiling solution of copper sulphate, verdigris, and water, to which sometimes potassium nitrate is added, until the desired patina is produced.

It may interest you to know that the Japanese are still adding to the number of their curious alloys, the last

addition being a variety of "shakudo" containing no gold. It has been introduced by my friend and former assistant Mr. Y. Koga for the preparation of medals for the soldiers who took part in the late war. It was decided by the Government that these medals should be made from the bronze guns which had been captured from the Chinese, but that "they must not present an undignified appearance like a cheap copper coin," but must have a black patina resembling shakudo. After several experiments he succeeded in producing an alloy with the desired patina by adding to the bronze of the guns small quantities of an iron arsenic speise termed "bajirome," containing 60 per cent. Fe and 32 per cent. As. The medals, after being struck and carefully burnished, are boiled in a solution of the following composition:—

Copper sulphate.....	2½ grms.
Verdigris.....	8½ "
Water.....	2½ litres.

After this treatment they possess a very fine black patina almost rivaling that of "shakudo." The above solution

does not differ very much from those generally used for shakudo, but it possesses this great advantage, that the burnished surface of objects treated by it is not in the least impaired.

Shibuichi.—Of equal or even greater importance than shakudo, and certainly in more extensive use in ornamental metal work, is the alloy of copper and silver called "shibuichi." Its name denotes that it consists of one part of silver in four of the alloy, *i.e.*, one part of silver is alloyed with three parts of copper; but it is rather a generic than a specific name, as under it must be included, not only two other definite alloys, *viz.*, "sambo-gin," consisting of one part of silver to two parts of copper, and "hoji-gin," composed of equal parts of each metal, but also several other lower and intermediate alloys. And in fact the alloy most generally employed by the chief art metal workers was not "shibuichi," in the strict meaning of the term, but "sambo gin."

The composition of the members of this group of alloys is given in the following table:—

ANALYSES OF SILVER ALLOYS OF THE "SHIBUICHI" GROUP.

	Hoji-gin.		Eiji-gin.		Sambo-gin.		Shiho-gin.	Ansei-gin.
	1. Mint Trade Bars. 1706 A.D.	2. Sword Mount. (Kalscher.)	3. Mint Trade Bars. 1710 A.D.	4. Mint Trade Bars. 1710 A.D.	5. Sword Mount. Early 18th Century.	6. Mint Trade Bars. 1711 A.D.	7. Mint Trade Bars. 1854 A.D.	
Silver.....	50.70	48.93	41.60	32.65	32.07	20.40	13.50	
Copper.....	49.18	51.10	58.32	67.27	67.91	79.58	86.48	
Gold.....	0.12	0.12	0.08	0.08	Trace	0.02	0.02	
Lead.....	0.52	
	100.00	100.15	100.00	100.00	99.90	100.00	100.00	

It will be observed that there is a great range in the proportions of silver present, from 13.5 to 50.7 per cent. The value of this alloy in decorative metal work is, like that of shakudo, entirely dependent on its patina. It possesses no special beauty when cast, its colour being that of pale gun-metal, or a common pale brouze, but when its surface is subjected to appropriate treatment it assumes a patina of charming shades of grey, which gives it a unique position among art alloys. No other affords the artist such a delicate, unobtrusive, and effective ground for inlaid designs of gold, silver, or other metals.

It was not known to the Japanese in mediæval times; in fact, it does not appear to have been used until much later than shakudo. The descriptions given of the ornamental appendages of historical swords even as late as the 17th century do not mention it, and the first record we have of the alloy only dates from the beginning of the 18th century (1706 A.D.), when it was used in the Government Mint for the preparation of debased silver bars, termed "chûgin" (trade silver), (analysis No. 1), which were used for commercial purposes. There are several examples of its use in sword-guards about the same date, but it seems then to have been chiefly employed as a substitute for a richer alloy, a pure silver surface having been given to it by the process I have already described, and not the fine grey patina of later times. The patina is produced by precisely the same operations which are practised for shakudo, the solution in which the objects are boiled having the same composition as that used for the arsenical bronze, with the addition of 1 c.c. plum-vinegar to each litre. I may say that all the alloys given in the table of analyses, including No. 8, yield a grey patina when treated with this solution, but the finest grey tints are only obtained with those containing from 20 to 50 per cent. of silver.

By the use in his designs of both these classes of alloys—shakudo and shibuichi—together with gold, silver, copper, and iron, the Japanese craftsman has achieved results in colour which are unrivalled in the metal work of the world.

The white of silver, the black of shakudo, the yellows of gold of various grades, the greys of shibuichi, and the reds

and browns of copper—all he employs in perfect harmonious combinations to enrich the effects of his sculptured work, and shows himself in all to be a true master in the art of metal decoration.

I have endeavoured to give you a brief account of some of the strange, unique, and primitive processes which have been practised by the Japanese for many centuries in the metallurgy of gold and silver. They are fast becoming obsolete, and will soon be forgotten. The age of steam and of griny works and factories has set in, and the craftsmen—to their credit, be it said—are rapidly adapting themselves to these new conditions, and are carrying out our Western metallurgical processes with as much zeal and skill as they formerly displayed in the old methods of the mediæval workshop.

The paper was profusely illustrated by diagrams, lantern slides, and specimens.

DISCUSSION.

In inviting discussion the Chairman said that he was sure the Section owed Mr. Gowland their warmest thanks for his very interesting paper. That was not the first occasion they had had to thank him for appearing amongst them. Though now resident in this country he had spent many years in Japan, and had come back with the most vivid recollections of what he had seen in that distant land. He (the Chairman) looked forward to his giving them, out of the abundant material at his disposal, further papers on metallurgy.

Mr. KERSHAW, referring to Mr. Gowland's statement that the pickling solution used for producing the very fine effects on the gold alloy shakudo contained 2 to 4 per cent. of gold, asked whether the same pickle was used for treating the shibuichi gold coinage. (Mr. Gowland: No.) He also wished to know whether the chemical action of the pickling solution in producing that decoration had been studied, and of what it really consisted.

Mr. GOWLAND, in reply, said that the composition of the pickling solution was sulphate of copper, verdigris, and water, to which sometimes potassium nitrate was added. As to the composition of the patina, Prof. Roberts-Austen

had worked on that, and it seemed to be a compound of copper and gold. On account of its extreme thinness it was very difficult to strip it from the metal, but he was still investigating it, and hoped at some future time to give its exact constitution.

THE ELECTRO-DEPOSITION OF ZINC.

BY SHERARD COWPER-COLFS.

MANY experiments have been carried out at different times with the object of cheapening the process of coating iron with zinc, and of avoiding the deterioration of the quality of the material which usually follows pickling and hot-galvanising, as the records of the Patent Office bear ample evidence.

Amongst these improvements are those based upon electrolytic methods. Most authorities recommend a current density of 15—20 ampères per square foot of cathode surface, at an E.M.F. of three volts at the terminals of the depositing bath, the solutions employed being zinc sulphate, acetate, or chloride, ammonium chloride or tartrate. An improved electrolyte invented by Herman has been tried on a commercial scale, the chief feature being the addition of the sulphate of the alkalis or alkaline earths to a weak solution of zinc sulphate.

I have obtained good, bright deposits from a solution composed of 10 oz. of zinc sulphate (sp. gr. 1.1770 = 19 per cent. of crystallised zinc sulphate) and 5 oz. of ferrous sulphate to the gallon of water, the anodes being of lead. The iron salts should be brought to the ferric condition, as no deposit of iron can be obtained from a solution of a ferric salt. The generation of hydrogen at the cathode reduces the salt to the ferrous condition, which is again converted into the ferric by the corresponding oxygen liberated at the anode; the formation of zinc sponge is thus considerably reduced. Thin coatings of zinc obtained from acid solutions under favourable conditions are very adhesive when proper care is exercised in the preparation of the receiving surface. I have here some specimens of zinced iron plate, double folded, and boiler tubes which have been reduced under the steam hammer to one-fourth their original length, the zinc coating being still intact and the weight of zinc per square foot averaging about $\frac{3}{4}$ oz. Electro-deposited zinc appears to adhere better to surfaces which have been cleaned with the sand blast than to surfaces which have had the scale and oxide removed with acid.

Fig. 1.

When zinc is deposited of a thickness corresponding to more than $1\frac{1}{2}$ oz. per superficial foot upon iron or steel, it does not form a continuous adherent coating. Attempts have been made by the late Dr. Leeson and others to overcome this difficulty in the same way as the want of adhesion in silver-plating was overcome, namely, by quickening—that is, immersing the copper or copper alloy in an aqueous solution of mercury; but in the case of iron the mercury has to be deposited electrolytically, as the iron will not

Fig. 2.

amalgamate with the mercury. Under unfavourable conditions the zinc coating is of a transitory nature, its durability being incompatible with hot-galvanising, as the deposit is porous and retains some of the acid salts, which cause a wasting of the zinc and rusting of the steel or iron. I exhibit some specimens of zinc deposited from an acid zinc sulphate solution which have been stripped from bright rolled steel; when held up to the light they will be

Fig. 3.

seen to be pierced with a number of small holes. On the other hand, zinc can readily be deposited free from pin-holes and ductile, having more the properties of rolled instead of cast zinc, when the proper current density and

strength of solution are carefully maintained. The presence of free acid appears to accelerate the formation of zinc sponge, as shown by the following experiments.

Each experiment was of about 17 hours' duration, the same solution and rolled zinc anodes being used in every case.

Fig. 1 shows a zinc deposit upon an iron cathode from a freshly prepared zinc sulphate solution, a fringe of zinc sponge having been formed around the plate at the water line. As the electrolyte apparently became more acid, so the amount of zinc sponge increased, as shown in Figs. 2 and 3.

Zinc electro-deposited upon iron and steel is found to resist the corroding action of a saturated solution of copper sulphate (Post Office Test for Telegraph Wires) as well, if not better than zinc applied by the hot or dry method. Fig. 4 shows the thickness of zinc required to withstand varying number of one-minute immersions in a saturated copper sulphate solution. Other matters of serious moment are the slowness of ordinary electro-zincing, the trouble experienced in coating articles of irregular shape, and the

Fig. 4.

Fig. 5.

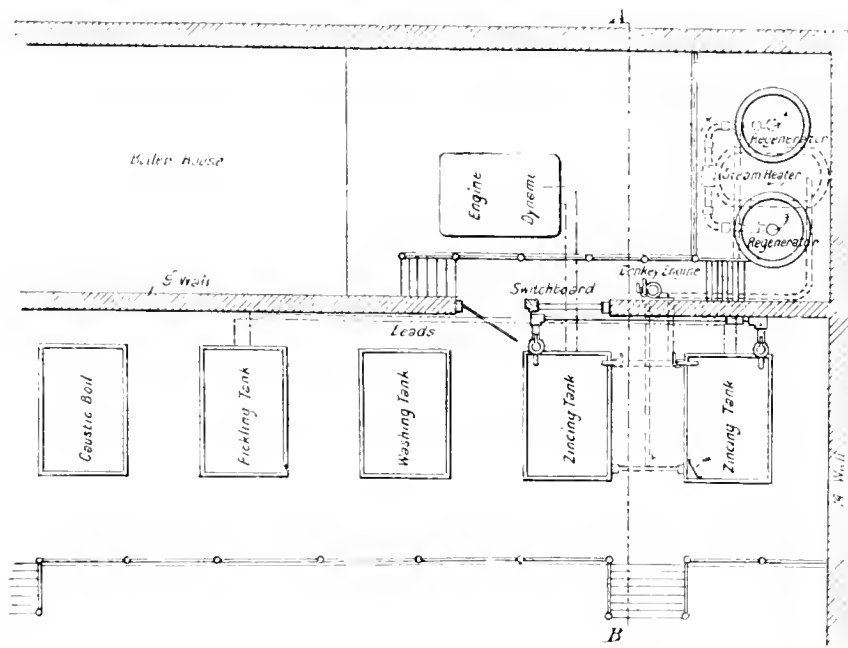

Fig. 6.

difficulties occasioned by the formation of loose, dark-coloured patches. These difficulties and the unhealthy non-metallic look of the zinc coating obtained by the humid process, its want of brilliancy and glitter, has prevented ordinary electro-zincing articles finding favour with engineers and the trade for many purposes.

Troubles are also experienced from the scaling and furring up of the anodes, the electrolyte constantly getting out of order when working with a large current density, as more metal is taken out of the solution than can possibly be dissolved from the anodes, on account of the rapid formation of an insoluble scale on the surface of the anode. The scale is constantly peeling off, and has a tendency to settle on the cathode, spoil the zinc deposit, and forms a thick sludge at the bottom of the depositing tank, rendering it impossible to circulate the electrolyte freely. I have found the loss of zinc in many cases to amount to 30 per cent. Figs. 5 and 6 show a plan and sectional elevation of a plant suitable for depositing zinc upon iron sheets. Two steel tanks are provided for containing the electrolyte, which is circulated through the regenerating tanks by means of a small donkey pump or a steam injector, the connections being so arranged that the regenerating tanks can be charged

and discharged alternately. In the regenerating tanks is placed from time to time zinc dust, which is dissolved by any free acid present.

The spent electrolyte is passed through a steam heater (shown on the sectional elevation, Fig. 6) before being injected into the bottom of the regenerator; the revived liquid, as soon as the undissolved zinc dust has had time to settle, is allowed to return to the depositing tanks by gravity. I have found the addition of zinc dust to the electrolyte to be the only practical method of keeping the electrolyte in working order, as zinc anodes—whether cast, rolled, amalgamated, or in the form of granulated zinc—fail to keep the solution up to its normal strength. The anodes which give the best results when working with zinc dust are lead. The economy effected by the use of zinc dust is considerable, as it can be obtained 7 $\frac{1}{2}$ or 8 $\frac{1}{2}$ per ton cheaper than rolled zinc anodes.

Figs. 7 and 8 illustrate a very convenient method of arranging the anode and cathode suspension bars, enabling the electrodes to be brought much closer together than would be otherwise the case; it also reduces the first cost of the plant, and forms a very stiff girder, which is an important feature when dealing with tanks 30 feet long.

Fig. 7.

SECTIONAL ELEVATION.

Fig. 8.

SIDE ELEVATION.

Figs. 9, 10, and 11 illustrate an arrangement of rotatable anodes adapted to conform to the irregularities of different

Fig. 9.

Cathodes

Fig. 10.

Fig. 11.

shaped articles. In Fig. 9 four anode bars are required, one cathode bar; in Figs. 10 and 11, three anode suspension bars and one and two cathode bars. This arrangement of anodes has been found very convenient for the zincing of various parts of sugar machinery.

The capacity of the dynamo for such a plant as shown in Figs. 5 and 6 would be 4,000 amperes at an E.M.F. of

7 volts, the current being conveyed to the tanks by bare copper strip having a sectional area of 1 sq. in. for every 1,000 amperes.

DISCUSSION.

Mr. F. PLATTEN wished to thank Mr. Cowper-Coles for his extremely valuable paper. It dealt with a matter of great interest, and would be read with more than ordinary care by people situated, as he was, in a district where

enormous quantities of the sulphate and other salts of zinc were annually run to waste. He would like to ask whether the electrolytic zinc was comparatively pure, as was the case with other electro-deposited metals, and particularly if the electrolyte must necessarily be pure; if not, it seemed to open up great possibilities for the utilisation of large quantities of impure oxide of zinc, for which, apparently, there was no market whatever. He referred chiefly to the oxides given off in reverberatory brass casting, which contained arsenic, antimony, &c. in appreciable quantities; and he would be personally much indebted to Mr. Cowper-Coles if he could give any information as to the action of these impurities in the electrolyte, or state if it was in any way analogous to the behaviour of the same bodies in a copper sulphate electrolyte, which has been very carefully studied. Mr. Cowper-Coles had stated that he considered a current density of 14 to 20 amperes per square foot to be most satisfactory; he (the speaker) found that with over 20 amperes there was a tendency to deposit trees of zinc round the edges and on the base of the cathode. He had tried to obviate this by dipping the cathode edges in wax, but the trees formed just the same at the junction of the wax and metal. Possibly the fact that copper cathodes were used might bear on the matter, but, curiously enough, the trees did not form at first, when the presence of a zinc and copper couple may have complicated the matter, but after a good, firm coating of zinc had been obtained. He thought if Mr. Cowper-Coles could elucidate these points, it might be of interest to the Society.

Dr. W. S. SQUIRE said that one very important factor had been omitted from the paper, namely, temperature. According to his experience the question of temperature considerably affected the deposit of zinc. At the freezing point of water a current density of 10 amperes per square metre would produce a good deposit, but as the temperature rose it seemed necessary to increase the density, until at the temperature of 30° C. the current density most favourable was about 200 amperes per square metre. As the current density increased so also must the electro-motive force be increased to get the current through, but not altogether in the same ratio, because the specific resistance of the bath would be to some extent diminished by an increase of temperature. Now the use of high electro-motive force to drive a large current through a given resistance would have the effect of warming the resisting liquid. That again would modify the conditions. It is clear therefore that some means should be adopted of keeping the bath at a constant temperature in order to obtain constant results. There was another point about which he would like to have some information. A lead anode is used upon which oxygen must be evolved. In the usual process of forming accumulators this results in the formation of peroxide of lead. If this took place in this process, the consequence would be considerable polarisation and counter electro-motive force, requiring increased electrical pressure to overcome it.

Mr. WM. THORP asked whether there was any explanation of the fact that the sand blast gave a better cleaning effect than the acid process.

Mr. W. F. REID wished to know whether any experiments had been made with regard to the durability of iron coated by the process just explained, when exposed to the atmosphere, especially in London. There was an essential difference from the ordinary coating produced by fusion. In the latter case there was an alloy of iron and zinc, as in tin-plating, which it was almost impossible to remove. With respect to the production of pure zinc from impure materials by electrolytic processes, there always seemed a difficulty on account of the spongy nature of the zinc produced, and he hoped that Mr. Coles had got over that difficulty. It was the chief difficulty in a process he had tried, a process which appeared to be good, but there was an enormous loss in running the deposited zinc down into bars. By putting half an inch of petroleum on the surface of the liquid, he found that the deposit was less porous. Unless overcome, this difficulty would render it difficult for this process to compete with the ordinary one.

Mr. COWPER-COLES intimated that he would send his reply to the discussion in writing.

The CHAIRMAN said that one remark in particular had interested him, namely, that the process was used in producing cube-sugar-making machinery. Anyone who had examined the articles put before them would see that the surface of the moulds was exceedingly smooth, and that was very necessary for casting sugar. When the moulds were galvanised in the ordinary way, their surfaces had very often to be coated with varnish to prevent the mass adhering to them.

In moving the customary votes of thanks to the authors, he wished to bid farewell to the Section as its Chairman. Dr. Messel had been elected to succeed him, and would, he was sure, fulfil the duties of the position in a thoroughly worthy manner. Speaking for himself, he could say that he had always had the interests of the Society at heart, and he thought that the record of work done during the session might be regarded as of a satisfactory character.

Mr. TYRER moved that the warmest thanks of the Section be given to Mr. Newlands for his services as Chairman during the past two years.

Mr. WM. THORP seconded the motion, which was carried by acclamation.

Mr. B. E. R. NEWLANDS briefly thanked the meeting for the cordial way in which the motion had been received, and concluded by congratulating his successor on the fact that he would have the able services of Mr. John Heron as Honorary Secretary of the Section.

Mr. S. COWPER-COLES, replying to Mr. F. Platten's remarks, said he had found zinc deposited from pure electrolytes to be free from impurities, but if much ferrous sulphate was allowed to accumulate, then considerable quantities of iron were deposited with the zinc. With reference to the formation of zinc trees, if the electrolyte were circulated rapidly, so as to produce skin friction, the formation of trees was much reduced. Constant temperature was necessary for good deposits; increase in temperature reduced the resistance and therefore increased the current. Nihusen had conducted some researches on this point of temperature and current density, and his latest views, as stated by Bocher, were opposed to those given by Dr. Squire as to the advantage of working at 0° C. Lead peroxide was formed when lead anodes were used, but the peroxide remained attached to the anode, and did not cause much loss of free acid. Probably the reason why electro-deposited zinc was found to adhere better to sand-blasted surfaces than surfaces which had been pickled, was that the rougher surface gave a better holding.

NOTES ON LABORATORY APPARATUS.

By J. H. COSTE.

An Air Bath.—This has been found useful for drying substances at temperatures above 100° C. It is usually difficult to obtain a temperature much above, say, 120° in the ordinary air-oven without using a large burner, which is generally difficult to regulate. The temperature also varies considerably at different heights in the oven. If the substance is attacked by air at high temperatures or gives off other substances than water, an estimation of the water is difficult.

The apparatus figured—which is made from a square "tin" or copper box, with a lid perforated at the top to take a thermometer (T), the bulb of which is level with the tubes (A and B) passing through the sides of the box—is heated by an Argand burner and supported on a retort stand. Dry air (or other gas) passes through the tube B, where it undergoes a preliminary heating, and then through the drying tube A. The substance to be dried is placed in a porcelain boat, or in a tube passing through the cork of A (by the latter means precipitates on filter tubes can be dried). It is usually sufficient to estimate the loss in

weight of the substance in the boat; but, if necessary, drying tubes can be used to collect the water, or special absorbing apparatus for other volatile substances.

A temperature of over 200° C. can be easily obtained with an ordinary Argand flame and maintained fairly constant. When a thermometer was placed *inside* as well as one *outside* the drying tube, it was found that the temperatures only differed by a few degrees when a water-pump was drawing air through the system at the rate of about 8 litres per hour. If this bath is protected from draught any temperature can be maintained within a few degrees easily.

A Glass Rod for Decantation.—It is often in quantitative operations desirable to wash a precipitate by decantation in a beaker or flask. If a long rod is used to pour the liquid down in transferring, it usually disturbs the settled precipitate in the beaker, and is inconvenient to place in a flask. A short rod, kept when not in use in a little beaker afterwards washed out into the main quantity, is liable to be neglected. A little rod bent at one end into a hook can be hung on the side of the beaker or flask when not in use, and thus cannot be overlooked in final washing, and at the same time serves for decantation purposes.

MR. F. J. R. CARULLA IN THE CHAIR.

ACETYLENE: LIMITS OF EXPLOSIBILITY OF MIXTURES WITH AIR, AND DETECTION OF SMALL PROPORTIONS IN AIR.

BY FRANK CLOWES, D.S.C.

(Summary.)

THE ease with which acetylene can now be prepared from calcium carbide has enabled the writer to determine the proportion of this gas which must be present in air to produce an explosive mixture. It was found that air containing any percentage proportions between 3 and 82, gained the power of burning throughout independently of the external atmosphere. This is a far wider range than that shown by any combustible gas yet experimented with, and it appears probable that the wideness of the range of explosibility, due to true combustion, is, in the case of acetylene, increased by its known power of undergoing endothermic decomposition.

The detection and measurement of proportions of acetylene in air which are less than 3 per cent., by the observation of the flame cap over a standard hydrogen flame, was found to be entirely satisfactory; and this method of detecting and measuring small proportions of inflammable gas in air seems to be one which is likely to be of use in certain laboratory processes of gas analysis.

Dr. Clowes showed comparative flames of coal-gas and acetylene, and also exploded definite quantities of acetylene and air, and showed the flame caps produced by smaller quantities than were required to form an explosive mixture.

DISCUSSION.

Mr. F. J. R. CARULLA said that in connection with the subject of acetylene explosions, Prof. Vivian B. Lewes had pointed out (*Journal of Gas Lighting*, May 12, 1896) that one of recent occurrence, originally involved in some mystery, was due to the presence of phosphide of calcium in the carbide obtained from the Continent, which contained this impurity owing to the use of phosphatic lime in its manufacture. Such carbide evolved phosphuretted hydrogen on contact with water, which doubtless fired an explosive mixture of acetylene and air. Prof. Lewes concluded his letter with the following caution, which was well worth quoting:—

"The present manufacture of acetylene from impure carbide, and the sale and use of automatic acetylene generators utterly unfitted for the purpose for which they are intended, is fraught with very grave danger; and I fear that in the next few months you will have to record many such accidents. This is the more to be deplored, as the undue haste to employ this most beautiful illuminant will only result in unjustly discrediting it."

Had Dr. Clowes any experience of this impurity in the carbide that he employed?

Mr. J. T. WOOD said that, when on the Continent, he had seen several acetylene lamps, and in Paris there was actually a little paper which was called *L'Acétylène*, which pushed the thing in an extremely vigorous way. There were articles in it about the gas every week—some of them good ones—and it appeared that they were shipping the carbide in large quantities from America. It was produced there by water-power from Niagara, and to compete with them under such circumstances in this country was quite hopeless, as they must inevitably produce it in America at a much cheaper rate. A friend of the speaker's had called his attention to an article in the *Figaro* of June 1st by a French chemist, M. Emile Gautier, in which he wrote about the "Domestic Uses of Acetylene." He made in the course of it some remarks about the gas being a paradoxical

body, and he said that if one tried experiments with it in small quantities by grammes and drops the risks in using acetylene were negligible, but when it came to using it in large quantities it was quite another problem. He went on to say: "To put water on to a mass of carbide equal to a dozen kilogrammes would be like lighting a cigar in a powder magazine!" He said: "On the other hand, acetylene can only be used when chemically pure, and that purity so far is only a myth." The object seemed to be to point out that the only way to use acetylene was in its liquid form. M. Raoul Pietet had been able to solve the problem in a very practical manner, and had devised a chemical means of purifying the gas and delivering it in a liquid form for use. He had also devised, though it would be too lengthy to explain in detail, a better means of using the solid form of carbide without danger of explosion. A company was being formed, or had been formed, to deliver pure liquid acetylene in the way that compressed gases were now delivered in this country. M. Gautier said that the problem was solved, and that acetylene in the future would put all other gas flames in the shade! Mr. Wood, in conclusion, said he would like to ask Dr. Clowes one question, and that was, that acetylene being such a curious body, and being able to explode without any oxygen, whether there was not some danger of its lighting back when burnt without a special jet?

Mr. R. M. CAVEN said there was one question he would like to ask with regard to the flame caps. Was not a flame cap a kind of local explosion? He supposed the lower explosion, from a standpoint of theory, was really a flame cap of infinite length.

Dr. CLOWES, in reply, said that there was no doubt that many of the accidents which had arisen from the use of acetylene had been due to the impurity in the carbide. The early reports, which came generally from the Continent, that when acetylene came into the air the gas would explode spontaneously, undoubtedly owed their origin to the presence of phosphuretted hydrogen. Phosphide had been found in the carbide and phosphuretted hydrogen in the gas, but they were now making the carbide sufficiently free from phosphide to be free from danger. The carbide they had been using that evening had been tested very carefully, and was certainly free from phosphorus. He was afraid that acetylene lamps on the Continent had, so far, not been very successful. A friend of his in Switzerland informed him recently that he had a lamp which would burn sometimes an hour and sometimes an hour and a half, and then would not burn again until it had been recharged; and that it generated the gas much faster than it could be burnt, thus leading to offensive pollution of the air. He had never found acetylene burning back in a cool tube. As they had seen in an experiment, they could get it to burn back when the tube was hot, but even then the store of cold gas was not fired or exploded. There was no doubt, as had been suggested, that the flame cap was simply the area of combustion maintained by the heat of the flame. If they gradually increased their quantity of combustible gas, the flame cap gradually merged into a mass of flame, and so became an infinite flame cap, but this was not permanent as an ordinary flame cap was.

THE AMOUNT OF AIR CONTAINED IN WATER.

BY J. M. C. PATON.

CONDENSING steam engines are in common use wherever supplies of water are plentiful. The water always contains some air and other gases, but about the quantity of the air and gases there appears to be some uncertainty.

Most writers on the steam engine content themselves by saying that "the water used for steam-engine purposes invariably contains more or less air, and if this were allowed to accumulate in the condenser the vacuum would gradually become destroyed," and they then give some empirical rule for size or proportion of air pumps.

If the water contained no air or gas, the function of the pump emptying the condenser would be simply to remove water, the volume of which is known; but this pump has also to remove an unknown quantity of air, and consequently in practice the sizes of the pumps are found to vary very much.

It is usual to define the size of the air pump as having a proportion or ratio compared with the volume swept by the piston of the steam engine.

At a recent trial of an American man-of-war with triple screw engines and independent air pumps, the pumps were found to have a volume ratio of 88·9, 75·7, and 61·6, or an average of 72 taken over the three engines. This ratio of 88·9 is the best of which I have a record. In this case, with a surface condenser, the air pump is removing all the water fed into the boilers, and also the air which leaks into the vacuum sections of the engine, but it is not dealing with the actual condensing water. In these pumps, with a ratio of 72 to 1, the feed water would only be about one-eighth of the volume swept by the pump pistons. The water entering the pumps from the hot well would be very free from air, and if it be assumed that this air occupied three-eighths of the pump capacity, then we have one-half of the pump capacity left to deal with the air due to leakage. In the present case this means that a pump having a capacity equal to 72 by 2, or $\frac{1}{144}$ th part of the volume swept by the piston of the low-pressure cylinder, is sufficient for the removal of air due to leakage. The efficiency of such a pump being, say, about 50 per cent., it follows that $\frac{1}{72}$ th represents the real volume of this air *in vacuo*. If this is divided by, say, 12, we find the volume of air at atmospheric pressure is about $\frac{1}{864}$ th part of the volume swept by the low-pressure piston. In the present case this means less than 10 cb. ft. per minute, or the total leakage area, is represented by a hole, say, about $\frac{1}{16}$ th of a square inch in cross section; this, with engines developing over 21,000 h.p. and including the leakage from about 20 auxiliary engines with their pipes and connections, must certainly be looked on as a satisfactory result.

Having now considered a favourable case where the condensing water does not give up its air to the pump, and having seen within what small compass leakages of air may be brought, we may now proceed to look into an ordinary case where the condensing water with the air it contains have also to pass through the air pump.

In ordinary horizontal condensing engines it is a very common practice to make the diameter of the air pump one-third of the diameter of the steam cylinder when both have the same stroke; in other words, the ratio of volumes is 9 to 1. (In special cases—for instance, in the tropics—the ratio may be even one-sixth instead of one-ninth.) Compare this with the 88·9 ratio found in actual practice under different conditions. The difference is caused by the presence of the condensing water and its air, combined with the need for a general design of such a character as to be able to deal with any ordinary or average conditions of working.

Speaking broadly, it may be said the air leakages are so small as to be almost negligible in good practice, and the air pump has to be designed to deal with the condensing water only; the usual margin for contingencies will cover all else.

The volume of condensing water is arrived at with practical accuracy by a very simple calculation when the working conditions are known, but for the present purpose we may say that in this country the quantity will usually be from 25 to 35 times the boiler feed water.

The question now arises, what quantity of air will enter the condenser with every 100 cb. ft. of water?

One authority on water analysis says: "Water is capable of absorbing, in a greater or less degree, every gas and every vapour which is placed in contact with it." All water which has been kept in open vessels is necessarily charged with nitrogen and oxygen gases, inasmuch as these gases form the chief constituents of the atmosphere. And if any sample of water be freely shaken up with large volumes of air, it will presently become charged with nitrogen and oxygen in certain well-ascertained proportions, depending on a physical law. A litre of water, freely shaken up with

large volumes of air at 15° C., will absorb 17.95 c.c. of air, the composition of which is:—

	Vols.
Nitrogen	65.1
Oxygen	34.9
	100.0

These figures agree with the theoretical amounts calculated on the coefficient of absorption of each gas, as given by Bunsen, viz., 0.0118 for nitrogen and 0.0299 for oxygen. $0.0118 \times 79 = 65.1$, and $0.0299 \times 21 = 34.9$.

The figures given deal with saturated waters, but in their natural condition many waters may be far from being saturated.

An old examination of Thames water at Woolwich showed carbonic acid 48.3 c.c., nitrogen 14.5 c.c., and oxygen 0.25 c.c.; total 63.05 c.c. Here the volume of oxygen is very small, owing to the presence of sewage.

Another examination of Thames water at Kingston showed total gases 52.7 c.c., formed of carbonic acid 30.3, nitrogen 15.0, and oxygen 7.4 c.c., thus indicating nitrogen and oxygen in about the theoretical proportions for fully aerated water.

The power of water to absorb gases increases with increase of pressure, but at present we are dealing with atmospheric or normal pressures only.

It will be noticed that the proportions of nitrogen and oxygen in the water are not the same as in ordinary air, but the amount of oxygen is greater. This point suggests that when these gases are given off *in vacuo*, the larger proportion of oxygen may to some extent account for the well-known rapid rusting away of wrought-iron bolts and nuts, &c. in the interiors of both condensers and air pumps.

I now repeat the question—What quantity of air will enter the condenser with every 100 cb. ft. of water?

Is water from ordinary sources usually fully saturated with air?

At the temperature found in a condenser, does the water give off carbonic or other gases in greater quantity than existed in a free state in the water before it entered the condenser?

The usual test for air seems to involve boiling the water. Does this give a correct report of the amount of gas in the cold water?

After water has given off its air in a vacuum, how much air does it take up during its passage through a tower of fascines, or other cooling apparatus, such as is used when the water is at once cooled and re-used?

DISCUSSION.

The CHAIRMAN said the question had been put in such a form that it really opened up a very big discussion. He would like to ask if there was anyone present who was prepared to answer the main question. If there was not, they must not think he desired to apply the closure, but he thought it would be desirable first to have the note printed, and then discuss it at the next meeting.

Mr. R. M. CAVEN gave some particulars and a table from Thorpe's Dictionary as to the gases dissolved in water. (See Thorpe's Dict. Appl. Chem., Vol. III., 964.) He said it had been thought that the small proportion of oxygen present in waters was due to the absorption of this constituent by oxidisable organic matter, but this could only apply to surface waters. The small quantity present in deep well waters which were free from organic pollution was a remarkable fact for which no explanation could at present be given. The large proportion of CO₂ in Thames and deep well water is due to calcium bicarbonate.

Volumetric percentage (or cb. ins. per 100 cb. ins.) of air dissolved in distilled water to saturation at 0° C. and 760 mm. pressure was as follows:—

N	1.580
O	0.824
CO ₂	0.716
	3.120

Soft waters were probably about saturated with N and O at their respective temperatures, though not with CO₂.

The discussion was then adjourned until the next meeting.

ERRATUM.

MR. C. RAWSON IN THE CHAIR.

TITANIUM OXIDE AS A MORDANT FOR WOOL. TOGETHER WITH A NOTE ON ZIRCONIUM AND CERIUM OXIDES.

BY JOSEPH BARNES, F.I.C.

MORE than 11 years ago I discovered the property which oxide of titanium has of combining with polygenetic colouring matters, and showed that it could be applied as a mordant to cotton in the same manner as alumina and would produce shades somewhat resembling those yielded by the latter substance (this Journal, 4, 310). In 1887 I dyed samples of cotton yarn by means of titanic oxide mordant, and these were exhibited at the Manchester Exhibition in the show case of Messrs. Kearns, Allan, and Co. No notice of these appeared in any of the English publications, but they were reviewed by Dr. O. N. Witt, in *Dingler's Polyt. Journal and Die Chem. Industrie*. Beyond this no mention has been made in any journal or text-book with reference to this property of titanic oxide. The reason why the matter has not attracted any attention is probably owing to the fact that the colours obtained on cotton presented no striking characteristics, and that they were no more than could be easily obtained by the use of commoner materials, and also owing to the generally prevailing idea that titanium was a rare element and one not likely ever to enter into serious competition with the common and easily obtained oxides of chromium, aluminium, and iron. Quite recently it occurred to me to try the effect of a titanium mordant on wool. The reason why this substance had been tried on cotton only was because I was at that time interested in the dyeing solely of vegetable fibres. I found upon making preliminary trials on wool that the oxide of titanium was really an excellent mordant for animal fibre, and was just as easy of application as those which are usually made use of, and further that it appeared to possess properties which would make it possible to produce shades which could not be obtained by any mordants hitherto employed. Then, again, there is the fact that the element titanium is much more abundant than is generally supposed, and that during recent years it has been found in very large quantities, and is now thrown away as a waste product. Having made a few more experiments with this substance, and having convinced myself that apart from the scientific interest which the question merits, that there is a probability of a commercial development in the use of oxide of titanium as a mordant, I thought it worth while to again bring the

subject before this Society, and to lay before it a few results which I have obtained in its application to animal fibre.

Oxide of titanium is said to be used in the manufacture of artificial teeth, and to enter into the composition of a certain glaze for earthenware; further than this I am not aware of any practical application to which it has been put, and seeing that this substance is one which has hitherto never entered into questions of practical interest to the dyer, I may be excused for occupying a little of your time in giving a brief description of its more important properties.

The element titanium has an atomic weight of 48. In the periodic classification it comes between carbon and zirconium, which form, together with cerium and thorium, the even series family of Group IV.—the odd series of the same group being silicon, germanium, tin, and lead. Its richest ores are rutile, or titanium dioxide, and titanate of iron, or ilmenite. Brookite and anatase are rarer forms of titanium dioxide. It is a very widely distributed element, and exists in much greater quantities than was formerly supposed. The number of minerals in which it is found is very great, and it has been shown to exist in the sun's atmosphere. Bauxite, a mineral which has of late years been obtained in large quantities in Ireland for the manufacture of sulphate of alumina, contains considerable quantities of oxide of titanium, varying from 2 per cent. to 10 per cent. A sample which I have here contains 6.42 per cent., the bulk of which, viz., 5.37 per cent., enters into solution along with the alumina when the ore is treated with vitriol, and is then reprecipitated as meta-titanic acid upon boiling the clear solution. Titanium exists, in more or less quantities, in most clays, and in some samples the amount is considerable. New Zealand magnetic iron sand, of which there are immense deposits, contains from 7 per cent. to 10 per cent. of oxide of titanium. According to recent investigations it appears that this element exists in notable quantities in the ash of many plants (C. E. Wait, Journ. Amer. Chem. Soc. 1896, 18, 402).

Of the better known elements, tin and silicon are most closely allied to it in the general habitude of their compounds, and titanium may be considered to hold an intermediate position. It may be obtained in the metallic condition as a dark powder by heating sodium in the vapour of titanium chloride. This powder burns, when heated in the air, with great brilliancy, and dissolves in hydrochloric acid, forming a violet solution of titanous chloride. This is a higher chloride than the tin chloride which would be formed under similar circumstances, and may be termed a sesqui-chloride (Ti_2Cl_3). Titanous chloride and, indeed, all titanous salts, are more prone to oxidation even than the stannous compounds. The anhydrous tetrachloride is produced by heating the oxide, mixed with carbon, in a current of chlorine. It is formed at a lower temperature than the corresponding silicon chloride. It may also be produced by heating the oxide in a mixture of chlorine and carbon monoxide. It is a heavy, strongly-fuming liquid, boiling at $136^\circ C.$, and may easily be obtained free from iron by distillation. When mixed with a small quantity of water it forms a solid oxychloride, which is soluble in a further addition of water. Alkalis throw down from this solution a hydrated oxide, which, unlike the hydrated oxides of tin and silicon, is insoluble in caustic soda or potash. It may be dissolved in cold mineral acids and in alkaline oxalates, fluorides, and tartrates. When its solution in hydrochloric or sulphuric acid is boiled, the oxide is reprecipitated in a different condition—as meta-titanic oxide. It is now no longer soluble in hydrochloric or dilute sulphuric acids, and has only a feeble attraction for colouring matters. It may be easily dissolved by means of hydrofluoric acid or by moderately strong sulphuric acid, e.g., by mixing with dilute sulphuric acid and concentrating on the water-bath.

A solution containing titanium gives, with tannic acid, an orange precipitate, with gallic and pyrogallie acids orange or brownish-yellow solutions, and with salicylic acid a pale yellow coloration. The action of hydrogen peroxide upon a solution of titanium is very characteristic

—a yellow to deep orange coloration is produced, which is destroyed by alkalis and restored by the addition of acid. The yellow and orange colours produced by salicylic and gallic acids and by hydrogen peroxide are imparted to wool when the latter is steeped in their hot solutions. The colour produced by hydrogen peroxide is supposed to be owing to a peroxide of titanium (TiO_2): it is destroyed after boiling some time.

Now with regard to the most suitable compound for the mordanting of wool, it is very obvious that solutions of the oxide in mineral acids could not be used without some addition to prevent the precipitation of meta-titanic oxide upon boiling. Oxalates, fluorides, and tartrates may be used for this purpose, and with all three I have been successful in the mordanting of wool. It is impossible for me to say, from the small number of mordanting experiments that I have made, what is the best material or the best proportion, or what are the best conditions generally, but I may say that so far I have met with most success in the use of the "tartrate." With the "oxalate" I found that the duration of heating and the temperature were most important things to attend to, and that, after heating for a certain time, the wool either lost the titanic oxide, or, what appears more likely, the latter became transformed into the meta or inert condition. Wool, when mordanted with the "oxalate," assumes a bright but pale yellow colour, and if taken out at this stage will dye up satisfactorily; if the heating be continued, the yellow colour disappears, and the wool will then give a poor result in the dye bath.

With the "tartrate" the wool may be boiled for an hour or two without this degenerative action taking place, at least to any serious degree, though I am inclined to think that even in this case there is a period of maximum efficiency and then a falling away. Wool mordanted with the "tartrate" mordant has a decided cream colour.

The question as to the best method of mordanting is, however, one that can only be settled by a long series of comparative experiments. The "tartrate" mordant that has been used for the patterns exhibited was prepared as follows:—

20 grms. of anhydrous titanium chloride were mixed with 80 grms. of cream of tartar and 50 c.c. of water. The mixture was then evaporated on the water-bath to a clear viscid residue, which, upon cooling, weighed 113 grms. From 20 to 25 grms. of this mordant were used for each 100 grms. of wool, and the mordanting bath was kept at the boil for about two hours. The dyeings were generally done with an addition of 3 c.c. of acetic per litre of dye bath.

The following is a list of colours thus obtained on wool:—

Alizarin gives a deep maroon.

Alizarin orange gives a bright scarlet.

Ceruleum gives a dark green, yellower than with a chromium mordant.

Alizarin blue gives a blue, redder than with a chromium mordant.

Logwood gives a deep black.

Tannic acid gives a deep yellow.

Salicylic acid gives a sulphur yellow.

All these colours except the last one withstand the action of dilute mineral acids and soaping. Even the logwood black and tannic acid yellow after soaking in dilute hydrochloric acid at $3^\circ Tw.$ for one hour, and then rinsed and soaped, suffered to a scarcely perceptible degree.

The behaviour of the mordanted cloth in the alizarin dye-bath is very remarkable; before the final maroon shade is developed, the cloth assumes a brilliant red colour, and if it is taken out at this stage and dried, it will be found to be nearly the same colour as that produced by alizarin orange. It is in this condition sensitive to acids, which turn it to a dull brown colour; washing and heating with water turn the brown colour to a maroon. The red colour withstands the action of the soap bath, and after this treatment it is much less sensitive to acids. When the red colour before soaping is heated with distilled water it gradually assumes a maroon shade. At first it occurred to me that this difference in colour was owing to a difference in ratio between the colouring matter and mordant, but dye tests made with varying amounts

of colouring matter and the same amount of mordant gave gradations in depth with little variation in tone.

With regard to the fastness of these colours to light, I may say that there has been no time to make thorough tests. Samples of the logwood black and tannin yellow have been exposed in a window facing the south from March 4th until the end of May and show no signs of fading. The colours which were dyed on cotton yarn and exposed in the Manchester Exhibition during the exceptionally sunny summer of 1887 showed no more tendency to fade than the corresponding colours on an alumina mordant, and the tannin yellow did not appear to suffer in the least, whereas the wood yellows were nearly bleached.

Oxide of zirconium, which comes next to titanium in the even series family of Group IV., has also an attraction for colouring matters, and when wool is boiled in a solution of zirconium sulphate it becomes mordanted with the oxide, and will yield with alizarin a colour very like the one produced on a chromium mordant. I have also prepared small pieces of cotton with a zirconium mordant, and obtained colours with alizarin and alizarin orange, the former yielding a reddish violet, and the latter a red.

Cerium does not appear capable of yielding a mordant to wool; when wool is boiled in a solution of a cerium salt, it will not take up any colour in the dye bath. I have produced colours on cotton with a cerium mordant, but they are quite worthless, being entirely destroyed by the weakest acid, and resembling in this respect the lakes produced by the alkaline earth metals.

DISCUSSION.

The CHAIRMAN said that these rare earths had not been much experimented with, and might turn out to be of importance. He suggested that if long-continued boiling deteriorated the mordanting, a better result might be obtained by "stuffing and saddening." He also remarked that the cloth had a somewhat harsh feel, and asked whether this was due to the mordanting.

Prof. J. J. HUMMEL remarked on the fact that oxalates, fluorides, and tartrates could be used as assistants, as in the case of the commoner mordants, and although the percentage of mordant used (25 per cent.) was rather large, it might prove possible to reduce it. The mordant seemed to be unique in being able to give such a brilliant colour as that produced with alizarin orange, and also one of such depth and fastness as that with logwood. The brilliancy of the colours with tannic and salicylic acids was certainly remarkable, and further experiments with titanium mordant in wool dyeing might be well worth carrying out. He pointed out that tannic acid might be considered as closely related to the yellow colouring matters, and the bright colour here given with tannic acid seemed to give distinct evidence of this relationship.

Mr. A. G. PERKIN suggested that the tannin might possibly be decomposed into gallic acid, which was known to give yellow colours with most mordants.

Mr. H. R. PROCTER inquired whether the tannin-yellow could be produced in the cold, as in that case it might probably find an application in leather-dyeing.

Mr. J. BARNES stated that cotton could be mordanted cold, and that probably this could be done with leather also. The attraction of the titanium mordant for tannia was so great that on boiling with tannin a sample of titanium-mordanted wool dyed with logwood, the logwood was partially discharged, its place being taken by tannin.

In reply to Mr. Rawson, he said that he had not tried the "stuffing and saddening" method. He had compared the fastness of titanium and chromium logwood blacks to acids, and found them nearly equal. Gallic acid produced a similar shade to tannin, but was not so fast. It could be dyed in a single bath, since no precipitate was formed by gallic acid with titanium, as was the case with tannin. He admitted that the titanium-mordanted cloth was somewhat harsh to the feel.

THE DYEING PROPERTIES OF CATECHIN AND CATECHU-TANNIC ACID.

BY J. J. HUMMEL AND REGINALD B. BROWN.

ANYONE who has studied the literature having reference to the application of catechu, must have been struck by the fact that very contradictory statements appear in text-books as to which of the two chief constituents of this dyestuff plays the more important part in the dyeing process. This uncertainty led us to make experiments on the subject, especially as we had at command a sufficient quantity of pure catechu, which had been prepared in the research laboratory of the dyeing department, by Mr. A. G. Perkin and Dr. Setzer. Moreover, a number of samples of various Indian cateches had been received for examination from the Imperial Institute, and it was thought that the investigation of the dyeing properties of these samples and of the constituents of catechu in their pure condition might suitably be undertaken at the same time.

The authors of many text-books appear to have derived their information from an earlier source, for we find the same statements couched in identical language in several works, while in no case are the actual experiments described on which the conclusions are based. All agree in describing catechu as containing (1) a colourless crystallisable body, insoluble in cold water, which is called catechin or catechuic acid; (2) a substance of the nature of tannin, perfectly soluble in cold water, and known as catechu-tannic, or mimotannic acid; and (3) other substances possessing a brown colour, and probably formed by the oxidation of one or both the preceding bodies, e.g., rubinic and japonic acids. Here agreement ends, and as regards the usefulness of these substances in dyeing, a variety of views are expressed. Kurrer (1848) states that the portion of catechu possessing dyeing properties is the catechin which, on oxidation, forms japonic acid, and that the catechu-tannic acid is without any influence on the production of the colour, since catechu from which all the catechu-tannic acid has been removed retains its dyeing properties unimpaired. The same statement, that catechin plays the chief part when catechu is employed in dyeing, is also made by Schützenberger (1867), Föl (1872), Crookes (1874), Singer (1875), and others. On the other hand, the claims of catechu-tannic acid to be the useful constituent for the dyer are upheld by Sacc (1861) and V. Joëlét (1879), while Napier (2nd Ed. 1875), Girardin, and Crace Calvert (1878) ascribe the dyeing properties of catechu to both constituents.

In view of these contradictions, we decided to make dyeing experiments with the pure substances, having regard only to the application of catechu in the dyeing of cotton. The crystallised and colourless catechin prepared in the research laboratory was considered to be absolutely pure, and the catechu-tannic acid employed, obtained from the firm of E. Merck, of Darmstadt, though not absolutely pure, having a pale yellowish-brown colour, seemed to be sufficiently pure for the present purpose. In the first instance we merely compared the dyeing properties of these two products with each other, and at the same time with those of commercial Gambier and "Bull-cuteh," as representing two widely different varieties of catechu. In the course of the experiments, however, further points of interest arose, notably the function of copper sulphate in the dyeing process.

In the ordinary method of dyeing catechu-brown on cotton, the material is steeped in a hot solution of catechu containing a small addition of copper sulphate, and subsequently allowed to remain in the bath as it cools. Without washing it is then treated in a boiling bath containing potassium bichromate, and for deep shades the dyeing and chroming operations are repeated. Our first experiments were carried out according to this process, and were conducted as follows:—0.5 gram. of each substance was dissolved in distilled water, and the solution, with or without the addition of copper sulphate, diluted to 50 c.c. In this solution a piece of cotton cloth $3\frac{1}{4} \times 2\frac{1}{4}$ in. in size, and weighing 0.5 grms., was boiled for one hour, and allowed to steep for one hour in the cooling liquor, then squeezed, and "saddened" in a bath containing 2 grms. $K_2Cr_2O_7$ per litre for 10 minutes at the boil. During these operations

the boiling liquors were maintained at a constant level. With half of each pattern the dyeing and saddening processes were repeated.

Experiment 1.—Catechin, catechu-tannic acid, Gambier and Bull-cutch were dyed simultaneously, according to the above method, with the addition of 0.05 gm. CuSO_4 to each solution. On comparing the results it was seen that the shades given by catechin and Gambier were similar, and much paler than those obtained from catechu-tannic acid and Bull-cutch, which were also similar to each other. The inferences to be drawn from this experiment are, (1), that both catechu-tannic acid and catechin possess dyeing properties, but the former to a much greater degree than the latter; (2), that Gambier behaves in dyeing exactly like catechin, while Bull-cutch behaves like catechu-tannic acid. The repetition of the dyeing and saddening operations very greatly increases the depth of colour; in fact, only in this way is it possible, according to our experiments, to obtain very full brown shades, an increase in the concentration of the cutch bath not sufficing for this purpose. It may be noted in passing that catechin dyed twice gives a very similar shade to catechu-tannic acid dyed once.

Experiment 2.—A repetition of Experiment 1 was made, omitting the addition of copper sulphate to the dye-baths. A similar comparative result was obtained, but all the shades were much lighter than in the first experiment. In this trial Bull-cutch dyed a deeper colour than an equal weight of catechu-tannic acid, and since it is of course impossible that the commercial product can be stronger in actual colouring power, so far as this is due to catechu-tannic acid, than the pure substance itself, this greater depth of shade might seem to be due to the presence in the cutch of small quantities of other colouring matters. The varying tones of brown obtained from different cutches might also be accounted for in this way. Having regard, however, to the fact that when dyeing with the addition of CuSO_4 (in Experiment 1), the depth of colour produced by catechu-tannic acid is slightly greater than that given by cutch, it is possible, and appears to us more probably correct, that the greater colouring power of the cutch in this experiment is due to its containing certain soluble-oxidation products intermediate between catechu-tannic acid and the insoluble brown colouring matter as fixed on the fibre.

It was noticed that catechin with copper sulphate produced a colour equal in depth to that given by catechu-tannic acid without this addition. It is therefore possible as suggested by Neubauer (1856) that under the oxidising influence of copper sulphate catechin is converted into catechu-tannic acid, and since the experiments show that the latter when dyed with the addition of copper sulphate yields a darker colour than without, it would appear as if catechu-tannic acid formed an intermediate product between catechin and the ultimate brown substance fixed upon the dyed cotton.

Experiments 3 to 6 were made with the object of ascertaining to what extent each step in the process contributes to the final depth of colour when dyeing with the pure colouring principles with and without copper sulphate. In each case one pattern was dyed for an hour at the boil, a second was allowed to cool in the bath, and with the third and fourth patterns the operations were repeated twice and thrice respectively. The patterns showed that the increase in depth due to steeping in the cooling liquor is very marked in the case of catechu-tannic acid but very slight with catechin; the latter is at once precipitated on cooling, and further absorption of it by the fibre is thus prevented. Catechin dyed without copper sulphate yields only a very pale brown, even after three times dyeing and saddening; after the first saddening the cotton has merely acquired a dull yellow tint, and it is possible that the colour resulting from repetition of the dyeing process may be due to catechin becoming partially changed in the dye-bath to catechu-tannic acid by atmospheric oxidation. In the case of catechin it is also noticed that the effect of chroming at each stage of the process is to make the colour much yellower and only very slightly deeper, the increased depth of colour due to repetition of the operations is therefore acquired during dyeing and not in the

saddening bath. With catechu-tannic acid the exact contrary is the case, an added dyeing operation merely makes the brown yellower in tone and very little fuller, while on saddening a great increase in depth results. It would seem therefore that the colouring matter in the form of catechu-tannic acid, which may provisionally be regarded as the more highly oxidised condition, is more sensitive to the further influence of oxidising agents, e.g., $\text{K}_2\text{Cr}_2\text{O}_7$, than when it is in the form of catechin.

It may be further noted that the results of these trials corroborate those of Experiments 1 and 2, the shades obtained by the use of catechin with the addition of copper sulphate, and catechu-tannic acid without this addition, are similar in depth, but the browns from catechin are redder before saddening and yellower after saddening than those from catechu-tannic acid.

Experiment 7.—Catechu-tannic acid and commercial Bull-cutch were dyed in the cold for periods of 1 and 16 hours without the addition of CuSO_4 ; it was here sought indeed to apply catechu-tannic acid to cotton under the conditions found most favourable in the case of tannic acid. On comparing the patterns with those of Experiment 2, which were dyed at the boil, it was seen that the shades differed little from each other. This result was by no means unlooked for, since in the absence of CuSO_4 one would naturally expect that only the soluble catechu-tannic acid would be utilised. By allowing the patterns to steep in the dye-bath overnight, instead of for one hour only, a slight increase in depth results, and here again it is possible that atmospheric oxygen during the prolonged operation acts like the copper sulphate of the ordinary process.

Experiment 8.—Patterns were dyed under exactly the same conditions as in Experiment 7, but with the addition of CuSO_4 to each dye-bath. Here no improvement is shown on prolonging the dyeing operation beyond one hour, all possible oxidation in the dye-bath being apparently effected by the CuSO_4 during the first hour. On comparing the dyed patterns with those obtained in Experiment 1, dyeing at the boil, very little difference in depth of colour was noticed in the case of catechu-tannic acid, but with Bull-cutch, which, of course, contains both catechin and catechu-tannic acid, the patterns dyed at the boil were considerably the deeper. This fact again indicates that in the presence of CuSO_4 both constituents of the cutch take part in the dyeing process.

Experiment 9.—It was thought possible that the greatly increased depth of colour caused by a repetition of the dyeing process was due to the attraction of further colouring matter by the chromic oxide fixed upon the cotton along with the colouring matter after once dyeing. In order to ascertain whether cotton mordanted with chromic oxide attracts the colouring matters of catechu, a piece of cotton was mordanted with chromium and divided into portions of the same size as those used in previous trials. These were dyed with catechin and catechu-tannic acid, and saddened with $\text{K}_2\text{Cr}_2\text{O}_7$; the colours obtained in this trial were in both cases considerably deeper than those dyed on unmordanted cotton; the explanation suggested may therefore be the true one. With regard to the use of mordants in conjunction with catechu, it was found that with aluminium mordants pure catechin dyes a dull light brown, and with iron mordants a more purplish brown, both colours becoming much yellower on subsequent treatment with $\text{K}_2\text{Cr}_2\text{O}_7$. Catechu-tannic acid yields with aluminium a brownish-yellow, with iron a dull light brown, and these shades are made much deeper by saddening with $\text{K}_2\text{Cr}_2\text{O}_7$, the former changing to a full red-brown, the latter to a yellowish-brown of medium depth.

There still remained to be considered the action of the copper sulphate in the dye-bath. If the idea is correct that it brings about the conversion of catechin into catechu-tannic acid, the question naturally arises: Is this change effected by virtue of the oxidising properties of copper sulphate, or is the presence of a metallic mordant in the dye-bath an essential feature of the operation? To solve this question, as far as it can be solved by dyeing experiments, it was necessary to dye with the addition of various substitutes for copper sulphate, some of which resembled this salt in containing a metal, others in possessing oxidising

properties, and to compare the patterns so dyed with those dyed without addition, and with the addition of copper sulphate. In choosing oxidising agents for this purpose, $K_2Cr_2O_7$ and ferric salts were necessarily excluded, since they precipitate catechin in the dye-bath. According to the result of the experiments, which were made with Gambier, the substitutes employed may be divided into three groups:

(1.) Substitutes which yield no useful result, the resulting colour being little or no deeper than when dyed without addition. In this group are comprised chrome alum, aluminium sulphate, zinc sulphate, sulphuric acid, and sodium carbonate.

(2.) Substitutes causing an increased depth of shade, but giving a duller and yellower shade of brown than that obtained with the use of copper sulphate. These additions were ferrous sulphate and potassium permanganate with sulphuric acid.

(3.) The colour is somewhat similar in depth and tone to that given by dyeing with the addition of copper sulphate. This was the case with hydrogen peroxide only.

We may therefore conclude from these results that copper sulphate is mainly useful on account of its oxidising properties, which, however, are not active enough under the conditions of the dye-bath to precipitate the solution. Non-oxidising metallic salts have little or no influence upon the shade, with the exception of ferrous sulphate, which resembles potassium permanganate in causing the production of a deep dull brown of a yellowish tone, a result probably due to a mordanting action of the iron and manganese respectively. Since, however, the pattern dyed with the addition of ferrous sulphate is lighter than the one obtained by the use of permanganate, the oxidising property of the latter is apparently not without influence on the depth of colour. The change in the dye-bath to which the increased depth is due is not brought about by either acid or alkali, and the only useful substitute for copper sulphate among those we have tried is peroxide of hydrogen, which, however, gives a shade somewhat lighter and redder in tone than is obtained by the use of copper sulphate. It has already been conjectured that in certain cases the oxygen of the air may act in the same way as the $CuSO_4$, although by reason of the slow action of the air the use of $CuSO_4$ could never be superseded in practice by atmospheric oxidation, at any rate, so far as dyeing with catechu is concerned.

A final experiment was now made to compare the effects of applying the copper sulphate and catechu *simultaneously* and *successively*, and for this purpose one piece of cotton was treated successively in separate baths with $CuSO_4$ and catechu, with a second pattern this order of operations was reversed, while two others were dyed at the same time with catechu alone, and catechu + $CuSO_4$ respectively; half of each pattern being afterwards saddened with $K_2Cr_2O_7$. On examining the patterns it was seen that the cotton treated with $CuSO_4$ and then with catechu was similar before and after saddening to that dyed without addition. As we expected, the preliminary boiling with $CuSO_4$ had no effect. On now comparing the results of applying the copper sulphate in the same bath as the catechu and subsequently to it, the former pattern was found to be much the deeper, and hence we conclude that the function of copper sulphate is to convert the colouring matter into some form in which it is most readily attracted by the cotton, and for this purpose it must be added to the actual dye-bath.

The conclusions to be drawn from our experiments may now be briefly summarised as follows:—In dyeing cotton with catechu the catechin and catechu-tannic acid both contribute to the production of the colour, the tinctorial power of catechu-tannic acid exceeding that of catechin. It is very probable that in the dye-bath catechin is converted into catechu-tannic acid by the action of $CuSO_4$, and it is therefore clear that a twofold oxidation is necessary, the addition to the dye-bath of a small quantity of some oxidising agent, e.g., $CuSO_4$, which does not cause precipitation of the colouring matter, and a subsequent oxidation in a separate bath with potassium bichromate. Having regard to these facts, our experiments show that the practical method of dyeing with catechu, viz., at the boil,

and with the addition of $CuSO_4$, is perfectly justified, for although the final product of the oxidation of catechin is the insoluble brown substance provisionally termed japonic acid, it does not appear that the oxidising action of the copper sulphate is energetic enough to produce this substance already in the dye-bath. Had this been the case, the use of copper sulphate in the dye-bath would have been injurious. The final and complete oxidation to insoluble japonic acid is reserved for the subsequent action of the bichromate of potash.

In examining the dyeing properties of the 29 samples of Indian catechu received from the Imperial Institute, it became evident that the differences observed in the dyed patterns corresponded to a certain extent to the differences shown by catechin and catechu-tannic acid in the foregoing experiments. The catechu samples were compared in the following manner:—10 grms. of each sample were extracted with water at $80-90^\circ C.$ for one hour, 1 gram. $CuSO_4$ added, and a piece of cotton cloth weighing 10 grms. entered into the bath. The above temperature was maintained with constant level for one hour, and the cotton allowed to cool for four hours in the liquor; at the end of this period one-third of the pattern was retained without further treatment, the remainder saddened for 10 minutes at the boil in a bath containing 2 grms. $K_2Cr_2O_7$ per litre. At this stage another portion of the pattern was retained, and the remaining third of the original piece was subjected to a repetition of the dyeing and saddening operations.

Judged according to their dyeing properties, the various samples of catechu examined naturally divide themselves into the following three groups:—

I. Cateches which, by the simple treatment of cotton in their decoctions at a high temperature, with the addition of copper sulphate, impart a more or less yellowish-brown and somewhat pale colour to the cotton, *not materially affected or darkened by subsequent boiling with bichromate of potash*, thus showing that little of the colouring principle of the catechu has been attracted by the cotton. If the two operations are repeated, these cateches give yellowish-brown possessing only a moderate depth of colour.

II. Cateches which in the first process stain the cotton a reddish- or orange-brown colour much fuller than that given by the members of Group I., and which by chroming are rendered distinctly redder and darker, an indication that the cotton has taken up a much larger quantity of the colouring principle than in the case of cateches belonging to Group I. By repeating the operations of "studding" and "saddening," the cateches of this group give a full rich reddish-brown dye much deeper than that given by the members of Group I. These cateches are apparently of the best quality for the purpose of cotton dyeing.

III. Cateches which in the first process give a comparatively pale yellowish-cinnamon colour, which is reddened by chroming. By repeating the operations of "studding" and "saddening" these cateches give reddish-browns, having little depth or body of colour.

On examination it would appear that the first group includes cateches Nos. 1-8 (see table below) all of which are of a somewhat pale brownish-grey internally, and show an earthy fracture. Nos. 9-12 may be reckoned as belonging to the same group, although they are dark brown in colour, show a lustrous fracture, and dye a somewhat redder shade of brown than the foregoing. From their appearance these cateches consist very largely of catechin.

The second group comprises Nos. 14-25, all of which are dark brown in colour, and have a lustrous fracture. These cateches being much more soluble in cold water than those of Group I., and giving darker colours, no doubt consist very largely of catechu-tannic acid. The third group includes the Gambier catechus, Nos. 26-28, which have a pale colour and earthy fracture, appearing to consist essentially of catechin.

In the table below, cateches Nos. 1-12 are arranged according to the shade given in dyeing cotton, No. 1 giving the yellowest brown, No. 12 the reddest shade.

Cateches Nos. 14-25 are arranged in order of depth of colour, No. 14 being the darkest and No. 25 the palest, though still a good colour.

Of cutches Nos. 26—28, the first mentioned gives the deepest colour.

Sample No. 13 gives only a grey stain and is evidently not catechu but, as stated on the label, an imitation, and appears to consist chiefly of mineral matter.

No. 29, which is not intended for dyeing, has similar properties to Nos. 26—28, but gives a much paler colour of comparatively little value.

For the purpose of comparison, cotton patterns were also dyed with the two following samples of catechu at present in the market:—

1. Bull-catechu.—This quality, which is said to represent the best in the market, has the form of large irregular blocks of a dark-brown colour and lustrous fracture.

2. Mangrove catechu.—This variety of catechu, which is probably derived from *Ceriops candolleana*, forms a very dark reddish-brown resinous mass, having considerable lustre, and being almost entirely soluble in cold water.

When dyeing with Bull-catechu the cotton is stained in the first operation a pale yellowish-brown, somewhat similar to that given by the members of Group I., but by chroming it became much darker and redder, behaving, therefore, like those of Group II. By repeating the staining and saddening operations a very full reddish-brown dye is obtained. The Mangrove catechu behaved during the dyeing

process very similarly to the Bull-catechu, the chief difference being that in the first operation the cotton is stained a very much redder shade than that given by any other catechu examined. These dyeing experiments show that the Bull and Mangrove catechus may be considered as belonging to Group II., indeed, they may be placed at the head of this class, since after twice dyeing they give much darker colours than any of the rest.

On comparing the results obtained from the various catechus with those given by catechin and catechu-tannic acid it was seen that those catechus which are brown in colour, lustrous, and more soluble in water behave in dyeing like catechu-tannic acid, while those which are paler in colour, with earthy fracture and less soluble, behave like catechin, of which they probably largely consist. Since catechu-tannic acid possesses greater colouring power than catechin, it is evident that the catechus which are more lustrous, more soluble, and richer in catechu-tannic acid are the most valuable for the purpose of dyeing cotton.

These notes must be regarded as a very partial inquiry into the application of catechu in dyeing, since we have entirely omitted any reference to the details connected with the use of potassium bichromate as the saddening agent, but this, and other points of interest concerning the use of catechu, we may possibly refer to in a future communication to this Society.

27	Cube Gambier (No. 2 best form).	".....	Similar to No. 26...	Similar to No. 26....	Similar to No. 26.
28	Block Gambier....	".....	Irregular lumps....	Outside, dark brown; inside, paler.	Fracture of outer portion of blocks, lustrous; of inner portion, earthy and powdery.
29	Gambier Papan (used for chewing).	Negri Sembilan..	Thin square cakes.	Externally pale brown, internally buff.	Very brittle, fracture earthy, showing brownish specks as if mixed with foreign matter.

Note.—Nos. 1 to 25 are derived from the *Acacia Catechu*, and 26 to 29 from the *Uncaria Gambier*.

DISCUSSION.

The Chairman, Mr. C. RAWSON, agreed with the authors that it was very hard to find definite information on this subject in books, and that the statements which were published conflicted. Some years ago he estimated the percentage of catechu-tannic acid in various samples of cutch, but found this no guide to their comparative value for dyeing purposes; this fact is evidently explained by the varying quantities of catechin and catechu-tannic acid contained in them. It was very difficult to compare cutch samples, owing to the different shades of brown given by different qualities. A further difficulty was, he had found, that in making dye-tests with certain samples of cutch the comparative value appeared to be different when different amounts of CuSO_4 were used. He would like to know if the authors had determined the amount of colouring matter in exhausted dye-baths by means of dyeing trials, and whether they had tried salts of vanadium in place of cupric sulphate; also whether copper and chromium were considered by the authors to form an integral part of the coloured body? It was well known that both oxide of copper and oxide of chromium were present in the dyed cotton. Had any experiments been made on wool dyeing with cutch? It had been suggested to use catechulin for wool dyeing and catechu-tannic acid for cotton dyeing, after separating the two by treating cutch with cold water.

Mr. T. FAIRLEY asked whether hydrogen peroxide was used in acid or in alkaline solution? Hydrogen peroxide would not act on certain substances except in presence of a third body; for example, if a solution of lead acetate were added to one of H_2O_2 and H_2S , lead sulphide was precipitated and immediately oxidised to PbSO_4 , showing that the H_2O_2 had no action on the H_2S prior to the addition of lead acetate. He asked also whether catechu might not be advantageously employed in wool dyeing to a greater extent than at present?

Mr. A. G. PERKIN said that in conjunction with Dr. Setzer he had been engaged for some time past upon an investigation of catechin. The results obtained by an examination of three samples of Gambier catechin and various specimens of *Acacia catechu*, which were among those experimented upon by Prof. Hummel and Mr. Brown, were that all these contained an identical catechin, melting at $171^\circ\text{--}172^\circ$ with decomposition. Schützenberger and Ruck (Bull. Soc. Chim. 4, 5) gave the melting point of catechin as 217° ; Etti (Monatshfte, 2, 547), 140° ; Gautier (Bull. Soc. Chim. 30, 568), $164^\circ\text{--}165^\circ$, and a second variety at $188^\circ\text{--}190^\circ$; and although those of low melting point were evidently impure specimens of that described above, the higher melting products were difficult to understand. The molecular weight of catechin appeared to be considerably lower than that usually given, and it was probably closely related to maclurin from old fustic, kinoïn from gum-kino, and cyanomaclurin which existed in jackwood. Results had been obtained by them, shortly to be described, which would give some insight into the constitution of catechin. He considered that the so-called japonic acid was probably distinct from katechuratin, and would like to know if any experiments with the dyed material had been made in this direction. Both catechu-tannic acid and katechuratin could be obtained from catechin without

apparent oxidation. Had the samples of mordanted cloth dyed with catechu been boiled for a long time? for by dyeing a short time he had obtained yellow shades somewhat resembling those given by kinoïn.

Prof. J. J. HUMMEL said that this paper had been brought forward in a somewhat immature condition, and that there were many other experiments which would have been performed had time permitted. Possibly the use of catechu in wool dyeing might be extended, but its use was limited by the facts that it made the wool harsh and prevented milling. The idea had occurred to him, before making the experiments just described, that the cutch might be separated into crude catechin and catechu-tannic acid in India, the former to be used by the colour manufacturer (since with certain azo compounds it yields useful colouring matters), and the catechu-tannic acid to be employed for dyeing. In consequence of these experiments he had abandoned the view which he formerly held, that the use of copper sulphate in the dye-bath was useless and irrational. It was further an interesting fact that the calico printer employed Gambier in preference to other varieties of catechu, although it was weaker in colouring power, the probable explanation being that gambier was of more definite strength and composition.

Mr. R. B. BROWN said that they hoped to make many of the experiments suggested by Mr. Rawson and others, and to embody them in a future paper. Hydrogen peroxide was used in neutral solution as a substitute for CuSO_4 . It had been frequently shown by analysis that cotton dyed with catechu contained both copper and chromium. Schlumberger held the opinion that the dye was a lake of chromium and oxidised catechu, while Heckmann considered that the chromium oxide was mechanically mixed with the oxidised brown substance. The cotton mordanted with aluminium and iron was dyed, like the other patterns, one hour at the boil and one hour cooling, and the shades were much browner than when dyed for a few minutes only.

THE HIDE-POWDER FILTER.

BY R. L. JENKS.

AFTER working for some time with the bottle form of hide-powder filter described by Mr. Procter in this Journal, April 1892, I have made a slight addition to the apparatus which it may interest other workers to make trial with. This still further diminishes the risk of loss of result caused by the tannin infusion creeping up the sides of the bottle instead of passing through the powder itself, and also economises the rather expensive hide powder. The improvement consists of a triangular tripod of small glass rod, which is made to fit inside the bottle. It is buried in the hide powder and acts as a conductor of the infusion up the middle of the filter.

The base fits the bottle loosely as an inscribed triangle, powder being pushed in between each point and the wall. The legs reach up about two-thirds of the distance to the shoulder of the bottle, but are so drawn in towards the centre as to divide the cross sectional area fairly equally into three parts. The infusion then travels up the glass legs as well as on the inside of the bottle, so that a cross section of the swollen plug of hide powder (easily expelled *en masse*)

from the bottle after use by blowing down the neck) exhibits three coloured rings in an outer zone. Some excellent patterns have been thus obtained. With 5 grms. of hide powder per 100 c.c. of infusion, containing 0.6—0.8 gm. of dry extract, the top half-inch or so is perfectly free from colour, showing that absorption is complete before reaching that point. About 1 gm. of powder is saved in each estimation, absorption is made regular, and the extra trouble involved is practically nil. For plugging the siphon tube I prefer glass wool to cotton wool.

The filter should be packed very lightly, and it is highly important that the liquor be added in small quantities, so that the powder is first moistened by capillarity, otherwise it is nearly sure to choke. Various other shapes of the "conductor" have been tried and considered (such as a spiral or helix, &c.), but the tripod pattern excels all others in strength, simplicity, and effectiveness.

1. Tripod in bottle.
2. Showing irregular creeping.
3. Plan of No. 1.
4. Cross section, showing regular absorption when tripod is used.

The names in italics are those of Members of Committee who retire at the end of the current session.

The following have been elected to fill the vacancies, and will take office in July next:—*Chairman: Prof. C. F. Chandler. Committee: M. Alsborg, W. F. Fuerst, A. H. Mason, W. Jay Schnefflin, and R. C. Schupphaus.*

*Meeting held at the College of Pharmacy,
Monday, May 18th, 1896.*

MR. A. H. MASON IN THE CHAIR.

THE EDUCATION OF CHEMISTS.

BY C. DUISBERG, OF ELBERFELD.

I do not wish to leave America, replete with new impressions and experiences which I have gathered here in the

interest of my business, without expressing, be it in only a small way, my gratitude for the abundant hospitality which has been offered me.

Chemical industry in America is yet in its infancy. It has not reached that height which we observe in England, France, and, above all, in my own country, Germany. What is chiefly wanted here is the organic chemical industry which in Germany is so highly developed. The foundation, however, of coal-tar distillation products has been laid here in powerful inorganic industries, and the time cannot be far off when there will be American competition in the organic chemical field, as is already the case with the special organic products of wood-spirit, acetic acid, acetone, &c.

I regret that I am not in a position to give you to-day a special report on one of the technological industries of my own knowledge. Since, however, the first condition for the growth and development of each industry is the education of capable men, due development can only advance step by step if clever, well-educated chemists can be found; and since chemistry, as an international science, is not limited by frontiers, the chemical industry of America can obtain capable Germans and the German industry capable American chemists and engineers. I can, therefore, without damaging our interests or those of our country, explain to you, as representatives of the chemical industry of the United States, my experience in the education of chemists.

I have at my command extensive experience regarding the education of chemists in all branches, for I am technical manager of one of the largest chemical manufactories in Germany—The Farbenfabriken, vormals Friedr. Bayer and Co., of Elberfeld, or rather of Leverkusen, near Cologne, whither now the whole works are being transferred in order to reduce expenses and to reduce the costs of manufacturing. We not only try to make use of all the derivatives of the tar from wood and coal for the production of aniline and alizarin dyestuffs of all possible descriptions, and also of very diverse pharmaceutical products, such as phenacetin, sulphonal, trional, salicylic acid, somatose (a new alimentary product), saccharine, &c., but we produce also the inorganic products necessary for their manufacture, such as sulphuric, hydrochloric and nitric acids, chlorine, &c., and a large number of intermediate organic products.

In our works there are at present about 100 chemists having a university education and about 25 engineers who have been trained at a technical high school. They are recruited from almost all the universities and technical high schools of Germany, and the greater number have been engaged by me personally during the last 10 years.

As member of the Commission formed last year by the German Society of Applied Chemistry for the introduction of a States examination for German technical chemists, I have often had the opportunity to exchange views regarding the education of chemists with numerous professors of the German universities and high schools, and also with a great number of gentlemen interested in chemical industry. I had a statistical table drawn up concerning the present education of chemists employed in the German chemical manufactories; this will be found later on in this paper.

No industry is so closely allied to science as the chemical, in which, it is true, one can arrive, though at a snail's pace, at new results without the use of scientific means; but in which definite results can only be obtained when the practitioners thereof are in close relation with the science, or, better still, when they are authorities in the special field chosen for their labours. He who in technical chemistry relies, without scientific support, on empiricism, is like the blind, who gropes his way along known thoroughfares, but cannot advance on unknown roads, and even if he succeeds after innumerable difficulties, passes along without noticing the points of interest.

Chemical reactions cannot be compared to an engine, in which every action is shown by the movement of the wheels, in which any irregularity is immediately visible, and can be observed at once by the engineer. In technical chemistry the sharp eye of a scientifically trained man is wanted in order to recognise the individual developments of the re-

actions in progress, which will only be seen through the accompanying indications.

Technical chemists find even in simple chemical reactions most remarkable complications, the prevention of which can only be accomplished in a prompt and sure manner by a chemist who is intimately acquainted with all the details of his science. For instance, it is generally thought that the production of an azo-colour is technically the most simple thing imaginable. It is only necessary to mix a certain quantity of diazo compound with a certain quantity of an amine or phenol, and the formation of the azo dye at once takes place quantitatively. But this is far from being the case. Certainly, if the right components be mixed, a dyestuff can be obtained, but since the struggle for economic production demands that quantitative yields of pure products shall be produced, it requires the concentrated work of a research chemist to determine all of the conditions that bring about the combination. In this case, the manner and form of the diazo compound, the manner and quantity of the solvent, the temperature and rapidity with which the two bodies come together and become chemically combined, the purity of the two components, are of the greatest importance. In the colour industry, even at the present time, in the manufacture of the simplest colours, the most important results are matured by constant observation, experimenting, and control during the process of fabrication.

In the other branches of chemistry the same conditions prevail. As an instance I may cite the manufacture of sulphuric anhydride and of fuming sulphuric acid; for, although the method of producing the latter substance has been known for years, it has been possible by constant observation and experiment to perfect the manufacture, so that the formerly expensive product is now sold at a much lower price. Ten years ago it cost about 20 times as much as concentrated sulphuric acid, but now it is so cheap that a fuming sulphuric acid of high percentage can be made by mixing the weak acid with sulphuric anhydride.

It is scarcely necessary to point out that for such an industry the education of its operators is of the greatest importance.

Chemistry, as a science as well as an industry, is, like electro-technology, a child of the 19th century. Technical chemistry, with its powerful influence on public life, only dates from the middle of this century, and started on its course of victory much later. It is therefore clear that the proprietors of chemical works, the representatives of chemical industry, are often not convinced of the necessity of employing in their works thoroughly well trained men of general scientific education. The consequences will, however, teach that all those who occupy the old standpoint and allow their chemists only a consultative branch in their laboratories must go back, or at least remain on the same spot, whilst others, who give qualified chemists the responsibilities of practical management and take advantage of the above lessons, go forward. In no other field is the saying "inactivity is retrogression" so applicable as in that of chemistry, where constantly new inventions replace the older, and where not only technology but science progress so quickly. Not only technical chemistry, but the other fields of practical chemistry, such as the chemistry of foods and analytical chemistry, require the best chemically educated powers in order to solve all problems quickly and exactly. This is specially important in all legal difficulties when the opinion of a technical chemist—an expert—is required. In these cases the judge has to rely on what the expert places before him, because chemical science and practice is too special a subject for the lawyer to penetrate thoroughly into the points.

A nation that will not stand back in the race must therefore pay the greatest attention to the training of chemists. How many young men lose their way in this respect, and never reach the aim of their ambitions? If they had had the proper training, success probably would be assured, but they are often directed into the wrong path.

The question is, how is it possible, according to our present ideas, to complete the education of a chemist, apart from the special field which, later on, he may make his own—whether he will devote himself to a scientific

career, or whether he will become a technical expert or an "alimentary" chemist?

I share the opinion of the majority of university professors and manufacturers who properly understand chemical science: in the first place, a thorough schooling, a general all-embracing education, is required. The justifiable reproach often made against young chemists is that they are one-sided, and that before they have acquired sufficient general knowledge they devote themselves to a special branch. It is, of course, not impossible to become a capable chemist without going through the usual schools, as has been shown by numerous living examples. This was especially feasible in olden times, when our science was still in its infancy, but now it is different. The almost incomprehensible advance that chemistry has taken of late years, the necessity for the right understanding of the influence of other sciences, such as mathematics and physics, physiology, pharmacology, &c., which all contribute to the attainment of the best results, necessitate a larger, more general, and extensive preparatory education. When the youth, after having gone through the best schools, where he has acquired a knowledge in general education, such as mathematics, natural philosophy, languages, literature, &c., goes to the university, he commits a grave blunder if he devotes himself immediately to chemistry to the exclusion of other sciences. Even at this stage he must not omit to enlarge his knowledge in other fields. He must keep himself informed of the general scientific progress in other departments at the university. He must study theoretical and practical physics in order to learn to understand the principles of physical chemistry. To that he must add mineralogy and crystallography, so that he may succeed in mastering inorganic chemistry, and train himself to understand the relation of substances to space. He should also know the foundation of botany and zoology to be able to follow the developments of organic life. His principal occupation must, of course, be theoretical and practical chemistry.

Chemical technology demands from every practical chemist a perfect knowledge of analytical chemistry, because it produces the best results, and is even of the most importance in organic technical chemistry. The young chemist, therefore, must become perfect in quantitative and qualitative analysis, without neglecting practical chemical work, and prepare for the field of inorganic chemistry. Inorganic chemistry is, scientifically and technically, the foundation of the whole structure of applied chemistry, and if the foundation is weak the whole edifice will surely suffer.

When analytical chemistry has been mastered, and the student is at home in physics, mineralogy, &c., he can safely study organic chemistry. Here the centre of gravity is in preparation work. The organic chemical student must make himself acquainted with all important methods from one, or, better still, several classical examples, which he learns from the great chemical classics. Here the young chemist is often wrongly advised, for he allows himself to be tied down to a special field, in order to assist his professor scientifically, before he has acquired an exact knowledge of organic chemical methods. We organic experts, as is well known, put the greatest value on this point, that, after a student has learned chemistry, theoretically and practically, he shall acquire the ability to independently work in scientific fields, so that he may find the way in unknown or unexplored chemical fields. The teacher must at this stage assist; he must keep the student from going astray, and should not interfere by his own action with the independence of the student's work. This is the best preparation for his profession as a technical chemist, because, later on, he will have to rely upon himself in chemical research and its developments, and also principally in devising new technical methods and products. The chemist, however, should not work independently until he has mastered methods, and when he has done so he should proceed alone, or he will only imitate, and not originate.

In theoretical chemistry the chemist should be thoroughly acquainted with chemical reactions, which form the basis of analytical methods, so that he can meet all the difficulties of technical analysis. Although inorganic

analysis has been much perfected, it still leaves much to be desired in technical questions, and is remarkably deficient in organic chemical industry. The young chemist must therefore learn also to find new analytical methods for technical practice. But, above all, he should be thoroughly acquainted with the chemical reactions that take place in the operation of technical chemical industry. I am an enemy of specialisation at universities, in whatever direction; for the young chemist, when beginning to study, seldom knows to what branch he will finally devote himself. The special field almost always depends upon accidental circumstances. For that reason we do not wish that the chemical technologist be taught, as often is the case, that the smallest detail of the apparatus is taken into account, and all the tricks, so to speak, that are wanted in some technical work are explained. We only wish that chemical technological sciences explain to the student practical inorganic and organic syntheses, for which they are—as, for instance, colour-technology—remarkably well adapted. We wish, of course, that the technical chemist should be acquainted with the great processes, such as those of *Le Blanc*, *Solvay*, *Deacon*, *Weldon*, &c., but only in broad principles, not in details of apparatus. Nor should he neglect physical chemistry, especially electrical. In the laboratories of all universities the young chemist should find electro-chemical appliances, not in special apartments, but in different places in the general working room, so that every student may be in a position to produce inorganic and organic preparations by electro-chemistry. The young chemist must learn to handle electric currents and know the principles of electrolysis. He will thus be placed in a position, if his way should lead him in an electro-chemical direction, to easily master that science.

In Germany the chemist generally finishes his studies with his promotion, based on his performance of a chemical experimental research, and after passing a verbal examination in the general field of chemistry, and in physics and mineralogic or another related science. He then obtains the title of Doctor of Philosophy or of Doctor *Rerum Naturalium*. This examination can be passed in Germany only at the university, and not at the technical high schools. These also serve for the education of chemists, although in a more technical direction, and the students generally finish their studies by passing the so-called "diploma examination." The young chemist is now ready to go into practice wherever a suitable situation is offered, and it will be easy for him to perfect himself in any special branch by studying the literature on that subject. If, however, he should have the necessary means and should not be compelled to work for his livelihood, he would do well, although his university study has cost him from four to five years already, to become assistant at the laboratory of a high school. He will strengthen in that way the knowledge that has very often been superficially acquired for the examination, and, before all and above all, he will exercise himself in independent practical laboratory work, but under the superintendence of the professor.

In our works in Elberfeld and Leverkusen, in which, for our special object, we choose almost exclusively young chemists from the high schools, we always give the preference to those who, after passing their examination, have worked one or two years with one of the professors with whom we are associated. When such a chemist joins our service we do not expect—if, for instance, he should enter the department of colours—that he should even know what a colour is. We have found it most satisfactory if we ourselves introduce the young chemist to our special field. For that purpose every chemist must first pass through our experimental dye and print laboratory, so that he learns dyeing and printing and becomes aware of the requirements of the dyers' industry as regards dyeing properties and the fastness of colours. When the chemist has finished in this laboratory he is introduced to the scientific laboratory, the function of which is to keep us and our chemists informed of everything new that appears in the field of our manufactures in literature, patents, &c., and it is at the same time principally the laboratory of inventions. In this our scientific laboratory alone at the present time more than 20 chemists are occupied.

Here the young technical chemist must produce a few of the well-known dyestuffs of the greatest variety of groups. He must experiment with those colours of our competitors that we find in the market, and only then will he slowly and gradually be directed into one special branch of colour chemistry. This scientific laboratory, similar to the general staff of the army, serves at the same time to supply us with substitutes for the leading chemists for special departments in our works, where only such chemists are admitted who have shown their value in the scientific laboratory.

In the same manner as we form our chemists for the colour department, we do it for other departments in our works—inorganic, pharmaceutical, analytical, &c.

We do not expect from any of the chemists during the first year of their appointment striking results. It will be satisfactory if he perfects himself as much as possible in the branch that has been allotted to him, and tries to master it. Capable, generally educated, active, and especially energetic men become almost always in the course of their first contract productive, and give the service that is expected from them.

I hear it said, however, that chemical industry works with numerous machines and apparatus. Innovations and improvements, especially in the field of inorganic industry, have been produced only by alterations and new constructions of furnaces and machinery. Is it not right, therefore, that the chemist, especially the leader of a department, should be educated in construction, in the knowledge of the machinery? Should he not be able to make drawings, and be capable, the same as an engineer, to construct the apparatus for his purpose? In many branches of chemical industry the knowledge of machinery may be necessary for the practical chemist, especially when the works are small and there are no engineers. In opposition to many of my friends I place myself, however, on the standpoint—although I myself have acquired this branch of technical knowledge—that the chemist does not require it as a necessity. Nothing, in my opinion, is worse than to make of a chemist an *ingenieur-chimiste*, as is done in France, or chemical engineer, as is very often done in England. The field of chemistry which the chemist has to master is at the present so enormous that it is practically impossible for him to study at the same time mechanics, which is the special field of the engineer. Division of labour is here absolutely necessary. I leave to the engineer and to the chemist their respective sciences, but I desire that both work together. I deny decidedly that any one person can master at present all necessary sciences and combine them in himself. The chemical engineer has some knowledge of both sciences, but his knowledge of neither is complete. That at least is my opinion and my impression. I also state that a thoroughly well trained chemist who has never heard of even the elements of mechanics, can find his way nevertheless very easily among the apparatus of chemical industry, most of which are simple, if he should be compelled to look after that part of his department. I personally prefer in questions of technical mechanics one capable engineer to a dozen chemists with a knowledge of mechanics. He, however, who places extra value on the knowledge of machines, and desires that his chemist should be instructed in this part, should not be too exacting in that direction, but be satisfied with a knowledge of the elements of this science, and take chemists that, as is the case with us in Germany, have been educated, not at the university, where those branches are not taught, but at technical high schools, where they must be learnt during the first years.

In order to see now whether those who conduct the chemical industry agree generally with the principles here laid down regarding the education of chemists, namely, that the knowledge of mechanics and construction is not required, I have issued statistical inquiries to 83 of the more important chemical works in Germany, in which more than one chemist is occupied, with the following results:—

Of 633 chemists, who find occupation in these 83 works (amongst which are 13 inorganic industries, 14 which manufacture organic intermediate products, 10 wood- and coal-tar distilleries, and 9 tin-colour works, as also 10 works for the manufacture of pharmaceutical products and 1

perfumes), there were 70 per cent. that had passed their examination at a higher German school—the gymnasium or other preparatory school, 45 per cent. that had received their education exclusively at the university, 17 per cent. exclusively at a technical high school, 35 per cent. both at the university and at the technical high school; so that when we divide the two last into equal parts, 65 per cent. had studied at universities and 35 per cent. at technical high schools. Of all these chemists, 68 per cent. had graduated as doctors of philosophy, and only 15 per cent. had passed the diploma examination of the technical high schools, whilst 15 per cent. had passed no examination whatever.

With reference to the different industrial branches, I found that the metal industries, the inorganic industries, the coal-tar distilleries, and the blasting-powder works, place those chemists who had been educated exclusively at the technical high schools on the same level as university chemists, but do not, as has been often thought, prefer them.

The other works, especially those that produce inorganic and organic products, the tar-colours, the pharmaceutical and perfumery works, seem, on the contrary, to prefer the university chemists, who know nothing about mechanics.

I am not sufficiently acquainted with the conditions of the United States to judge, but I am firmly convinced that the requirements I have described for the education of chemists in Germany are also applicable, and perhaps still more so than with us, considering that there the principle of division of labour is more accentuated, and where also chemical industry is beginning to develop itself in various ways.

In so highly developed an industry as modern technical chemistry is now in Germany, in which at present chemists, physical experts, physiologists, physicians, apothecaries, engineers, architects, and even jurists—as, for instance, in our works in Elberfeld—are combined, one can only expect good results by reasonable division of labour and concerted action when all concerned are first-rate powers; when, above all, the chemists, who of course form the majority, are energetic, active men; when everyone in his special branch is an authority. This applies not only to Germany, but must apply equally to all other competing countries.

Chemists who have to spend from five to six years in their education naturally ask high salaries, but it will be found that the capital so invested will produce good interest.

Although our great master and poet Goethe says:—"All theories are grey, but the golden tree of life is green," it is necessary in chemical industry that all who take part in it should study both theory and practice. The search after the philosopher's stone, which occupies the modern chemists now just as much as in the times of our forefathers, the alchemists—with this difference, however, that the definition of what is meant by the philosopher's stone has been altered,—is in the present time scarcely possible by empiricism. Only he will find this philosopher's stone who provides for himself and his co-operators the highest qualifications in general and special, theoretical and practical education—activity and energy.

DISCUSSION.

The CHAIRMAN said the meeting was indebted to Dr. Duisberg for telling them in forcible language the secret of Germany's success in chemical industries. In some countries better provision was now being made for that education which alone can bring about these results.

Dr. SCHIEFFELIN said he had experience for three semesters in a German university studying chemistry, and could testify to the tremendous importance which was attached to thoroughness in chemical work as a preparative for entrance into technology. The mere fact that the larger manufacturers of coal-tar colours employed as many as 100 doctors (graduates of the university were all doctors, which meant that they had studied at least two or three years longer than the graduates of American colleges) was convincing. A man in America who got the degree of Bachelor of Philosophy from the Columbia School of Mines, or from Yale, the Sheffield Scientific School, or from any of the numerous and excellent schools of techno-

logy, was about two years behind the man who had really earned his degree of Doctor in the Germany university; and, as Dr. Duisberg had pointed out, after they had obtained this degree they were expected to work two or three years as assistants in the laboratories of the technical high schools. Nearly every important city had a technical high school, which corresponded pretty closely to schools of technology, such as were found in Hoboken, the Stevens Institute, the School of Mines, the Troy Polytechnic, and the Massachusetts Institute of Technology, &c. There were also a number in the West. These young men went as assistants to the professors in these schools of technology, and learnt practically a great deal about making reagents and directing the students how to study elementary chemistry there; and he supposed it was evident that a man learned a great deal more by teaching another than in superficially learning to recite to another. Prof. Chandler told him that in the new laboratory in Columbia College (about to be built by the generosity of the Havemeyers) there would be arrangements whereby all the students would prepare their own reagents, so that they would have some technical and practical education as well as theoretical. When he (Dr. Schieffelin) was in the School of Mines, from 1883 to 1887, reagents were made by the laboratory servants, under the direction of the assistants and professors in the private laboratory, and students did not really know very much except what could be picked up, yet they were supposed to know theoretically how to prepare them. But the boys who went there in the next few years would learn a great deal more than he did, and it was a very significant and pleasant fact that the American schools were overtaking the foreign ones in this respect, and he was sure that the necessity of thorough education in chemistry was being more and more appreciated by all of our manufacturers here. He thought that the testimony of them all would be that they saw the value of employing the most highly educated men in chemistry they could get. It was only to-day he cut out from the *New York Times* about a third of a column testifying to the value of the investment of chemical research for the purpose of showing it to his partners, in order to persuade them that some of the outlays, which are theoretical, that were being made at our laboratory (for electrolytic application) are really very good investments for the future. If one bought machinery purely for experimental purposes, it seemed to the men with old-fashioned ideas as rather extravagant; but it was not extravagant in the end, for in a few years not only would the interest on the investment be saved, but the whole cost.

Prof. COBLENTZ said this paper of Dr. Duisberg's impressed him very much, coming from such an authority, who had had experience in selecting and training so many chemists at such a large factory. It must be acknowledged that the Germans were exceedingly thorough; that before they took up any speciality in chemistry, the chemists got a foundation in all the allied branches; but the difficulty that Americans laboured under, in his experience so far as it goes in teaching, was that if Americans wanted to be chemists, they wanted to be so quickly, and they did not want to bother about learning the theory of chemistry. They would even go to work and take young men before they have passed out of the schools, and say, "I want a chemist made of my son." The young man was sent into a college, which harried him through, and he came out an analytical, an organic chemist, able to get on fairly well in that one speciality, but always labouring under the disadvantage of inadequate training; and Americans would never be able to compare with Europe until the requirements of the institutions were stricter. Another point that struck him as true, and which came within his own experience, was that German professors had their own hobbies, and liked to get the students on these hobbies as soon as possible. He was often taken from the preparation of organic compounds and set to work on one of these hobbies, and never knew what he was doing or in what direction he was tending, but he had to work on that hobby nevertheless. He thought that one disadvantage some of their German brethren laboured under was that students often had to work on these hobbies without being allowed

to complete their necessary preliminary educational training in that line. On the whole, this paper was a valuable contribution to their knowledge, and he thought the schools throughout the country should apply this lesson, and have students thoroughly trained in theoretical education in all necessary branches, and then let them take up specialties.

Dr. ECCLES was reminded of a speech of a professor in England not long ago, in which he pointed out one important feature of the difference between England and Germany. The professor said an Englishman first discovered the aniline dyes in England. The Germans had built upon the foundation laid by England, and had beaten England in their own field. Inquiry into the cause of this resulted in the declaration that it was the thoroughness with which Germany was educating its chemists. Dr. Duisberg's paper forcibly reminded him that the general tenor of educationalists throughout America to-day was in the same direction. They insisted upon students in every field being thoroughly posted in the fields undertaken by them. They pointed out the fact that it was habit that made the man; that if a habit of careful thorough work was established in him, he would not break away from it. Slovenliness of thought or manipulation once established becomes habitual and detrimental. The strength of a chain was gauged by that of its weakest link. So with mental links. When strain was put upon the student the weakest point of his education was that which determined his success. If he had been well trained and had paid due regard he would become a true chemist, if chemistry was the lot he had chosen.

There was, however, a danger to be considered lest the field should be made too wide and the thoroughness too intense in everything in which they wanted to train them. One consequence would be that before the foundation was laid manhood would have come, and possibly old age, and before the structure was erected their opportunity might have passed. That might be avoided by limiting the amount of preliminary study in such a way that the things studied should be preparatory to those likely to be required in the future. The Doctor emphasised this in his paper. The simple lesson was that all could take in chemistry by this method of division of labour. This was the lesson of the future for the teacher. A century or more ago every professor was expected to be a professor of astronomy, physics, languages, mathematics, of everything. He was supposed to fill the whole field of science and know it all. That had passed away. They now left out things that were no longer necessary for study, and the consequence would be that in these new fields they would have to do precisely as with the sciences: find what could be discarded. It was just as necessary to do this as to be thorough in what they undertook.

Dr. McKENNA said all felt the need of more thoroughness in their educational methods, and the paper and subsequent remarks that thoroughness must begin lower down was a most useful warning to educators. The fact that their science was so beautiful, its principles so broad, so all-embracing in their nature, proved the necessity for "broad" study in preparation; studies of languages, literature, the "humanities" as they were called, and students who had spent sufficient time at this "broadening" study would certainly absorb the so-called strictly scientific knowledge with greater ease and produce better men. He agreed with Dr. Coblenz about the great hurry in which characterised the American student. That perhaps was the greatest fault with the young men, an overweening desire to rapidly get over the ground, to reach success very early, but without due preparation success would be deferred.

Mr. KENT thought they had scarcely made the most of chemical industry. Their industries had so far been in the cruder materials. They had taken the agricultural, the soil, the forest, the mines in their primeval conditions, and had hardly been prepared to establish chemical industries. That was one phase of the case, another was the commercial conditions met with, such as the tariff. That alone had been an obstacle, in his opinion, in chemical industry, also the expense of labour. Labour was expensive, and the man pursuing chemical industry needed the assistance; that and the development of literature and of our institutions, the classes, however, advanced had then energies

occupied in laying the foundations, in getting in materials to work with, and they had scarcely time to give to chemical industry the attention which the subject demanded.

Dr. HORN observed that one point which struck him very forcibly was the generosity of spirit displayed by Dr. Duisberg and the Company in taking the trouble to complete the education of these young men whom he was testing, so to speak, and it was an example which might be followed very advantageously by those employing chemists, to teach not only those, but the workmen, the reasons for the work which they do. A number of striking instances of this were brought to his notice, where it might have redounded to the advantage of the employer if he had been careful to be somewhat generous in the instruction of his workmen as well as of his chemists. He thought also that the younger teachers who have not always had the advantage of instructing the graduated chemist, or the advantage of so many men in their employ, should do all that possibly can be to encourage those who work in our laboratories to follow out the studies that pertain to their daily work. He had found always that even the youngest boys in the laboratories, who do the most elementary work, were generally enthusiastic, and if once pointed out they very quickly profit by the instruction. A case came to his notice not long since of a man in a sugar refinery who let a large tank of sugar solution become quite acid through fermentation, and on asking him why he had not put lime in it, he replied that "he knew they put lime in the tanks up stairs when they got acid, but he did not know they put it in down there." It had never been explained to that man that the lime was put in to counteract the progress of the fermentation. Workmen are not instructed why certain things are done, when very frequently no possible harm would result from such instruction. Dr. Duisberg had given good examples of the good results which flow from a generous view of this matter.

Dr. PROCHAZKA fully endorsed the policy of Dr. Duisberg, though the adherence to such policy had not been emphasised in that country, because no chemical works of that magnitude existed. Personally he was engaged in a kindred industry, and in engaging a new chemist his policy was the same. He cared far less for what the chemist claimed to know in the particular industry than for his possibilities.

Mr. PLATT said the best testimony to the value of Dr. Duisberg's paper was the fact that it struck everyone present differently. He was not a scientific man, but an employer of labour, skilled and unskilled; he agreed that they did not make enough of their chemists. It had been his aim to obviate the misapplication of the chemist's possibilities; and because a man was scientific and had a university degree it was no reason why he could not be a practical business man also. They had good evidence of that in Dr. Duisberg himself.

The CHAIRMAN: Dr. Duisberg referred to the possibilities of the chemical industries of this country in the future. One of the great advantages which America had to-day was that it could begin where Germany now stood; but it was necessary to have the institutions of education to enable them to do the work, so that if some of the merchant princes could have been present to hear this address they would have seen that to be generous in this matter would be a good investment for the welfare of the country and therefore for themselves. One of the charms of this paper to him had been the strong point the author made of their having no secrets among the employes in Elberfeld. Now if they went into any chemical works in other parts of the world they would find there were some departments to which they could not gain entrance, and in days gone by they were told that certain secrets had died with certain men. Now in Elberfeld they heard there was nothing of that kind.

One would like to ask Dr. Duisberg how much it costs in Germany to obtain this education? What fees had a man to pay before he becomes a doctor of science, and also what inducement there was for him afterwards in the way of salary, besides the possibilities of glory that might arise from original research; and to ask this because they found so many German chemists coming to America. It might

be a great advantage to have them, that they might carry on the work which they left behind in Germany in branch establishments in America, when the time for such development arrived.

Dr. DIETBERG said he never heard a discussion in English before. He was very interested in hearing the different points on education in America, and was very surprised to hear, especially from Prof. Coblentz (and it seemed to him the principal point), that young chemists hurry in learning chemistry. They in Germany had no difficulties in quite the same manner. He had stated in a German paper that when about 17 years ago he went to the university, he had to work in organic chemistry even the second semester; then he preferred to go to another university, and six semesters afterwards (three years) he took his degree. He did not enter in the technical department, but went to Munich and Strasburg and studied further, and only after finishing the theoretical systems perfectly he went into technical chemistry. American students appeared to be anxious to become perfect chemists quickly and to get money. It was the opposite in Germany. There were a great many chemists, and not three, but perhaps five, six, seven years were necessary to perfect the students and enable them to become doctors now. But their educational system was still being perfected, and the aim would be that no student should be allowed to study chemistry until he had passed an examination in the school to show his general education; and even then he would not be allowed to go from the university to take a degree until he had accomplished some original research, which was the point of greatest importance. Dr. Horne was right in telling them that German works trained their chemists themselves; that was the best way, they thought, and they had to do it, not only with young chemists, but with occasionally older ones. It was necessary, because every man when he had to do technical work became tired. He had to work from morning till evening, when his domestic duties claimed his attention, and it was impossible for him to read novelties in patents, in literature, &c. Therefore all these novelties were brought to the chemists in the works. There was every two weeks an assembly of all the chemists of the works, where the chemists of the scientific laboratory and special departments had to tell the other chemists what they had read in their several branches, what they had found in common, and in this way they were enabled to give perhaps in three or four hours a perfect review of every new thing that had happened in the fortnight.

In answer to the question, how long they spent in training a young chemist, he had already stated that it was perhaps one year. They did not educate the chemist, but he had to educate himself by working in the laboratory necessary for his branch. They did not expect success the first year, but they got success in following years. A student in Germany had to study, say, five to six years now, and the cost of this was perhaps 10,000 to 15,000 marks, for which a student could educate himself in the university, and live very well. 10,000 to 15,000 marks was necessary because the study of chemistry was not very cheap. Large sums for experimental work, fees for the lectures, &c. had to be spent.

The point which he understood Mr. Plant to make was that Americans did not place sufficient confidence in their chemists. That was a very bad feature. Earlier, in Germany especially, the foremen of the works occupied the first place, and the chemists the second. The chemists had to work in the laboratory, and the foremen and workmen had to manufacture the colours; but that was now changed. Now the foremen had nothing to say about chemistry work and manufacturing colours. The chemist alone had to decide in all these cases, and that was of the greatest importance.

But if their Chairman told them that there were many secrets in other countries and that there were no secrets in the works in Germany, he was entirely mistaken. There were a great many secrets in German works, but in the circle of the factory there were only a small number. Still, no person was allowed to tell the secrets he knew and heard. He had to keep them to himself. Naturally in the

special departments of the works there were secrets which were known to special chemists, because in some ways it was necessary—when impossible to protect a process by patent—to keep it secret.

Dr. SCHIEFFELIN desired, before closing the discussion, to refer to the Chairman's remarks upon the necessity of endowments for research in chemistry in America. It would be ungrateful to the late Peter Cooper if he did not testify to the value and great importance of the Cooper Institute in New York. Some of the best men in his factory, when they were boys and young men, and up to within a few years, and on showing interest in chemistry, were advised to attend the night school in chemistry for three years in Cooper Union. His firm were very glad to pay the slight expense of 15 dols. or 20 dols. for apparatus (the tuition being free), and they got a most excellent foundation in chemistry,—as good as a great many graduates of the technical schools, chiefly because they had an interest in the work. That led him to point out that the graduates of the German universities were on a rather different footing from the graduates of American technical schools. The great number of students in the German universities who studied chemistry never graduated and never got the degree of Doctor. They went out and had a good time, and did not work in the laboratory or take trouble to experiment, and as they did not try they did not get their degree. The men who did graduate in America had a pretty thorough foundation. For instance, the class of 1887 of the School of Mines were 95 freshmen; of that number only 33 graduated, but the class that graduated numbered 45 because they had some 12 who had fallen from the class above into that class. And so in Germany the weeding-out process went on, and probably only those of best ability went into the colour works; and as for secrets, he had always understood that workers at neighbouring desks did not even know what their neighbours were working at. They were partitioned off. Probably in the happy family of the works, they were told about it. As for Peter Cooper and his work they could not be too thankful for New York having such an institution.

ON THE ANALYSIS OF WHITE PAINTS.

BY G. W. THOMPSON.

THERE are upon the market, as is well known, numerous brands of white paint, ground stiff in oil, and sold as "strictly pure white lead," which are mixtures of various materials, more or less inferior to, and selling at prices much below pure white lead. The analysis of these mixed paints is not ordinarily considered difficult, and with certain mixtures this is true; but there are mixtures on the market on which chemists have obtained very materially divergent results. To speak of these peculiar mixtures was our primary intention, but on further thought we have considered it advisable to take up the whole subject of mixed white paints. It is not our purpose to consider the examination of the oil, or the vehicle in such paints, but only the pigment or solid constituents. The solid proximate constituents used are as follows:—White lead, so called sublimed white lead, consisting of varying proportions of lead sulphate, lead oxide, and zinc oxide, lead sulphate, zinc oxide, barytes, sulphate of lime, carbonate of lime, china clay, silica, sulphide of zinc, sulphite of lead.

There may be other constituents used in this class of paints, but so far as we know, the above list is practically complete. The steps in their analysis are as follows:—

- 1st. Extraction of oil.
- 2nd. Preparation of extracted sample for analysis.
- 3rd. Qualitative examination.
- 4th. Ultimate quantitative analysis, showing elements present.
- 5th. Proximate quantitative analysis, showing the forms in which these elements are combined.

The extraction of the oil may be performed by using any solvent for oil, which is completely volatile at 212° F. We prefer to use C.P. benzol, as it may all be distilled off, and nearly all recovered, and because its solvent action is superior to that of turpentine, benzene, or petroleum ether. We perform the extraction by treating about 20 grms. of

the paint in a small beaker, decanting four times. In the presence of much zinc oxide, a small and insignificant portion of this substance will fail to settle, and will be carried over with the solvent. The extracted paint is dried at 212° F.

The dry paint so obtained is ground in a porcelain mortar, and passed through a 50-mesh screen so as to obtain a uniform sample from which to weigh out.

The qualitative examination for the elements present may be performed as follows:—Effervescence with concentrated hydrochloric acid indicates carbonic acid, sulphuretted hydrogen if zinc sulphide be present, or sulphurous acid if lead sulphide be present. These latter two may be recognised by their odours. Boil a portion of the paint with a solution of acid ammonium acetate, filter, and test portion of filtrate for sulphuric acid with barium chloride. Test another portion of the same solution with sulphuric acid in excess for lead, and if precipitate of lead sulphate be obtained, filter off, and test filtrate for zinc by making alkaline with ammonia, and adding ammonium sulphide. Test another portion of ammonium acetate solution for lime by making alkaline with ammonia, adding ammonium sulphide, filtering, and adding ammonium oxalate to filtrate. The portion insoluble in ammonium acetate, in the absence of sulphide of zinc and sulphate of lead, may be barytes, china clay, or silica. The qualitative examination of this residue is best combined with quantitative examination given further on.

The oxides and elements the presence of which is usually possible in a white paint are:—Carbonic acid, water (combined), sulphuric acid, sulphurous acid, sulphur (combined as sulphide), silica, barium oxide, calcium oxide, zinc oxide, and zinc combined as sulphide, lead oxide, aluminium oxide.

The actual determination of these constituents is not in all cases necessary, and many short steps may be taken; thus, in the absence of sulphuric acid, the lead soluble in acetic acid may be directly calculated to white lead. We think it best, however, to give here suggestions for the determination of the separate constituents given above. We would determine carbonic acid by any accurate absorption method. Water cannot be determined accurately in samples from which the oil has been extracted, as a small amount of organic matter will remain which vitiates the results. In the absence of sulphites and sulphides, it may be approximately determined by obtaining the loss on ignition, and deducting the carbonic acid from it; the remainder is water, but the results so obtained are always high. In some cases it may become necessary to take the water by difference. The method of obtaining the water by absorption, used by some, is inaccurate because of the empyreumatic substances given off on heating and absorbed with the water. Sulphuric acid may exist in two conditions, in one it is soluble in ammonium acetate and in the other, as in barytes, it is insoluble in ammonium acetate. That soluble in ammonium acetate may be determined by precipitating with barium chloride in that solution. Sulphuric acid in barytes is best calculated from the barium present determined as described later. Sulphurous acid may be determined by oxidation to sulphuric acid, or its determination may be based on the insolubility of lead sulphite in ammonium acetate. For instance, one portion of the sample is oxidised with nitric acid and the total lead determined. Another portion is treated directly with ammonium acetate and the lead soluble in that menstruum determined. The difference between the two determinations is the lead present as sulphite, from which we may calculate the sulphurous acid present. Sulphur as sulphide is always present as zinc sulphide, which is never used in the presence of lead compounds. It may be determined by oxidation with bromine water and precipitation with barium chloride, or by determining the zinc insoluble in ammonium acetate. Silica may be determined by treating matter insoluble in ammonium acetate with hydrofluoric acid and sulphuric acids. The loss on ignition is silica, or it may be determined by fusing the residue in the regular way. Barium oxide is determined by precipitation with sulphuric acid from hydrochloric acid solution of that part of fused residue insoluble in water. Calcium oxide by precipitating in alkaline or acetic acid solutions with ammonium oxalate,

weighing as oxide or sulphate. Zinc oxide is precipitated as carbonate in the usual way. To secure a uniformly fine granular precipitate, we have found it useful to finish the precipitation with bicarbonate of soda, and then boiling to expel excess of carbonic acid. Lead may be determined as chromate in acetic acid solution by precipitating with bichromate of potash and weighing in Gooch crucible. Alumina from fusion of insoluble residue is determined in the usual manner. Schemes for the separation of these constituents from each other and into their proximate combinations depends on the constituents present, and we can treat this subject in no better way than by taking typical cases, which we now do.

Sample 1 is a mixture of barytes, white lead, and zinc oxide.

Two 1-grm. portions are weighed out. One is dissolved in acetic acid and filtered, the insoluble matter ignited and weighed as barytes, the lead in the soluble portion precipitated with bichromate of potash, weighed in Gooch crucible as chromate, and calculated to white lead.

The other portion is dissolved in dilute nitric acid, sulphuric acid added in excess, evaporation carried to fumes, water added, the zinc sulphate solution filtered from barytes and lead sulphate and precipitated directly as carbonate, filtered, ignited, and weighed as oxide.

Sample 2 is a mixture of barytes and so-called sublimed white lead.

Weigh out three 1-grm. portions. In one determine zinc oxide as in case 1. Treat a second portion with boiling acetic acid, filter, determine lead in filtrate, and calculate to lead oxide. Treat third portion by boiling with ammonium acetate, filter, ignite, and weigh residue as barytes, determine total lead in filtrate, deduct from it the lead as oxide, and calculate the remainder to sulphate. Sublimed lead contains no hydrate of lead, and its relative whiteness is probably due to the oxide of lead being combined with the sulphate as basic sulphate. Its analysis should be reported in terms of sulphate of lead, oxide of lead, and oxide of zinc.

Sample 3 is a mixture of barytes, sublimed lead, and white lead.

Determine barytes, zinc oxide, lead soluble in acetic acid and in ammonium acetate, as in case 2; also determine carbonic acid, which calculate to white lead, deduct lead in white lead from the lead soluble in acetic acid, and calculate the remainder to lead oxide.

Sample 4 is a mixture of barytes, white lead, and carbonate of lime.

Determine barytes and lead soluble in acetic acid (white lead) as in case 1. In filtrate from lead chromate precipitate lime as oxalate, weigh as sulphate, and calculate to carbonate. Chromic acid does not interfere with the precipitation of lime as oxalate from acetic acid solution.

Sample 5 is a mixture of barytes, white lead, zinc oxide, and carbonate of lime.

Determine barytes and white lead as in case 1. Dissolve another portion in acetic acid, filter, and pass sulphuretted hydrogen through the boiling solution, filter, and precipitate lime in filtrate as oxalate; dissolve mixed sulphides of lead and zinc in dilute nitric acid, evaporate to fumes with sulphuric acid, separate, and determine zinc oxide as in case 1.

Sample 6 is a mixture of barytes, white lead, sublimed lead, carbonate of lime.

Determine barytes, lead soluble in acetic acid and in ammonium acetate, as in case 2, lime and zinc oxide, as in case 5, and carbonic acid. Calculate lime to carbonate of lime, deduct carbonic acid in it from total carbonic acid, calculate the remainder of it to white lead, deduct lead in white lead from lead soluble in acetic acid, and calculate the remainder to oxide of lead.

Sample 7 contains sulphate of lime.

Analysis of paints containing sulphate of lime present peculiar difficulties, from its proneness to give up sulphuric acid to lead oxide or white lead if present. Sulphate of lime and white lead boiled in water are more or less mutually decomposed with the formation of sulphate of lead and carbonate of lime. A method for the determination of sulphate of lime is by prolonged washing with water with

slight suction in a weighed Gooch crucible. This is exceedingly tedious, but thoroughly accurate. A reservoir containing water may be placed above the crucible, and the water allowed to drop slowly into it. This may take one or two days to bring the sample to constant weight, during which time several litres of water will have passed through the crucible. Another method for separating the sulphate of lime is by treatment in a weighed Gooch crucible with a mixture of 9 parts of 95 per cent. alcohol and 1 part of glacial acetic acid. Acetates of lead, zinc, and lime being soluble in this mixture, the residue contains all the sulphate of lime and any sulphate of lead and barytes which may be present. Determine the lead and lime as in sample 4, and calculate to sulphates. Sulphate of lime should be fully hydrated in paints. To determine this, obtain loss on ignition; deduct carbonic acid and water in other constituents; the remainder should agree fairly well with the calculated water in the hydrated sulphate of lime, if it is fully hydrated. If, after washing a small portion of the sample with water, the residue shows no sulphuric acid soluble in ammonium acetate, the sulphate of lime may be obtained by determining the sulphuric acid soluble in ammonium acetate and calculating to sulphate of lime. The difficulty is in determining the sulphate of lime in the presence, or possible presence, of sulphate of lead. To illustrate the analysis of samples of white paint containing sulphate of lime, and the difficulty attending thereon, we would mention a sample containing sublimed lead, white lead, carbonate of lime, and sulphate of lime. In such a sample we would determine the lead, lime, sulphuric acid, carbonic acid, loss on ignition, the portion soluble in water, and the lime or sulphuric acid in that portion, calculating to sulphate of lime. Deduct the lime in the sulphate of lime from the total lime, and calculate the remainder to carbonate of lime; deduct the carbonic acid in the carbonate of lime from the total carbonic acid, and calculate the remainder to white lead; deduct the sulphuric acid in the sulphate of lime from the total sulphuric acid, and calculate the remainder to sulphate of lead. The lead unaccounted for as sulphate or white lead is present as oxide of lead. Deduct the carbonic acid and water in the carbonate of lime and white lead from the loss on ignition, the remainder being the water of hydration of the sulphate of lime.

Sample 8 contains as insoluble matter, barytes, china clay, silica.

After igniting and weighing the insoluble matter, carbonate of soda is added to it and the mixture fused. The fused mass is treated with water, and the insoluble portion filtered off and washed. This insoluble portion is dissolved in dilute hydrochloric acid, and the barium present precipitated with sulphuric acid in excess. The barium sulphate is filtered out, ignited, weighed, and if this weight does not differ materially—say by 2 per cent.—from the weight of the total insoluble matter, the total insoluble matter is reported as barytes. If the difference is greater than this, add the filtrate from the barium sulphate precipitate to the water-soluble portion of fusion. Evaporate and determine the silica and the alumina in the regular way. Calculate the alumina to China clay on the arbitrary formula $2\text{SiO}_2, \text{Al}_2\text{O}_3, 2\text{H}_2\text{O}$, and deduct the silica in it from the total silica, reporting the latter in a free state. It is to be borne in mind that China clay gives a loss of about 13 per cent. on ignition, which must be allowed for. China clay is but slightly used in white paints as compared with barytes and silica.

Sample 9 contains sulphide of zinc.

Samples of this character are usually mixtures in varying proportions of barium sulphate, sulphide of zinc, and oxide of zinc. Determine barytes as matter insoluble in nitric acid, the total zinc as in case 1, and the zinc soluble in acetic acid, which is oxide of zinc. Calculate the zinc insoluble in acetic acid to sulphide.

Sample 10 contains sulphate of lead.

This is of rare occurrence. Sulphate of lead is insoluble in ammonium acetate, and may be filtered out and weighed as such. It is apt on exposure to the air in the moist state to become oxidised to sulphate of lead.

There are certain arbitrary positions which the chemist must take in reporting analyses of white paints:—

1st. White lead is not uniformly of the composition usually given as theoretical (2PbCO_3), (PbH_2O_2), but in reporting we must accept this as the basis of calculating results, unless it is demonstrated that the composition of the white lead is very abnormal.

2nd. In reporting oxide of lead present this should not be done except in the presence of sulphate of lead, and if white lead is present, then only where the oxide is more than 1 per cent.; otherwise calculate all the lead soluble in acetic acid to white lead.

3rd. China clay is to be calculated to the arbitrary formula given.

In outlining the above methods we have in mind many samples that we have analysed, and the combinations we have chosen are those we have actually found present.

ACCURACY IN SILVER ASSAYS.

BY FREDERIC P. DEWEY.

I wish to call attention mainly to one source of inaccuracy in assaying, which, though well known and easily corrected for, has until recently been largely neglected. I refer to the absorption of the precious metals by the slag and cupel.

Mason and Bowman have published a table giving the average loss of silver in the entire process of scorification and cupellation as 2.54 per cent., 0.55 per cent. in scorification, and 1.99 per cent. in cupellation.

For gold the average for the entire process was 0.87 per cent.—0.574 per cent. in scorification and 0.296 per cent. in cupellation. But the meagre description of the results impairs their value.

At the April, 1894, meeting of the Washington Chemical Society I presented a paper on "The Accuracy of the Commercial Assay for Silver," in which I called particular attention to this matter.

In this paper are given many results on various materials ranging from tailings from silver mills carrying from 1.8 to 18.5 oz. of silver per ton through various ores, both raw and roasted, from 12.5 to 45.5 oz. per ton, lead carbonate precipitates from 1 to 500 oz. per ton, base sulphide precipitates from 100 to 5,000 oz. per ton, regular sulphide precipitates from 100 to 16,000 oz. per ton, base bullion from 300 to 500 fine, and lastly, fine bullion averaging 999.3 fine.

The following table summarises some of the results:—

Material Assayed.	Grade of Value.	Range of Inaccuracy.	Average Inaccuracy.
		Per Cent.	Per Cent.
Tailings	1-20	18.0-18.6	13.7
Washed ore	15-35	13.0-10.0	10.4
Raw ore	20-50	16.0-5.0	9.7
Roasted ore	20-45	12.0-6.0	9.1
Lead carbonate	50-100	5.1-2.6	3.8
Base sulphides	1,000-5,500	5.0-1.8	3.0
Regular sulphides	2,000-16,000	2.8-1.2	1.7
Copper-silver bullion, 300 "fine"	2.0	2.0
Fine bullion, 999.3 "fine"	1.1	1.1

In general the percentage of the inaccuracy of the ordinary commercial assay from slag and cupel absorption varies inversely with the value of the material assayed, when figured upon that value.

In order to see this most clearly it is necessary to compare results of the same class of material, and, preferably, made by the same assayer under practically constant conditions. Sometimes, when a series of individual results differs irregularly, if the results are grouped considerable regularity may appear. For instance, on looking at a series of miscellaneous results on ores running from 15 to 40 oz. per ton, no irregularity may appear, but if the results are grouped in periods differing by 5 oz. per ton they may become very regular in the variation. While different assayers working on the same material may show some regularity they may also vary greatly.

When, however, high-grade material, such as sulphide precipitates running from 8,000 to 16,000 oz. per ton, particularly if they contain much copper, are assayed, the results are not always so regular in their variation.

When we come to consider the percentage of inaccuracy when figured upon the total material assayed, we find that it generally follows the silver contents of the material, and in the case of rich products, becomes very large. Thus, in 2.3 oz. tailings, the silver equals 0.0079 per cent. of the total, and a 21.8 per cent. loss on this equals only 0.0017 per cent. of the total. On the other hand, in a 17,500 oz. sulphide, the silver equals 60 per cent. of the total, but the comparatively small loss of 1.25 on this equals 0.756 per cent. of the total.

The following table gives a few results upon this point:—

Material.	Grade.	Silver Inaccuracy Per Cent.		
		Per Cent.	Of Total.	Of Silver.
	Oz.			
Tailings.....	2.3	0.0079	21.8	1.0017
Ore.....	20.3	0.0305	8.9	0.0062
".....	30.5	0.1011	5.0	0.0051

While the amount of silver recovered from the slag and cupel in the case of ordinary ores is small, when stated per ton of ore; yet when a year's operations, involving 10, 20, 30 or more thousands of tons, are considered, the difference between an ordinary and a corrected assay amounts to quite a respectable sum, and becomes well worthy of consideration in these times of low prices for silver.

When we consider rich materials, such as high-grade ore and the products of the Russell process, for instance, the slag and cupel loss on a single ton becomes considerable; and with very rich products, such as lixiviation sulphides, particularly when they carry a large percentage of copper, as in the regular Russell sulphides, this loss may amount to several hundred ounces per ton.

The assay of Russell sulphides presents unusual difficulties.

They are precipitates obtained in the lixiviation process of treating silver ores. In general they carry 8,000 to 14,000 oz. of silver per ton, 20 per cent. to 33 per cent. of copper, a little lead, some free sulphur, and the balance various impurities in small amounts. The variety that I am most familiar with carries about 1 oz. of gold for each 1,000 oz. of silver. They are very disagreeable to handle; they are light and dusty; they soil everything they touch, and yet they are sometimes semi-malleable. On account of their richness, but small weights can be taken for assay, and even then large buttons of silver are obtained which are given to spitting, and the presence of so much copper requires the use of large amounts of lead.

After much work, the following method has been elaborated as the most suitable for their assay, and is used in settling contracts for handling the sulphides:—

"Weigh out one-twentieth of an assay ton of sulphides, 55 grms. of granulated test lead, and 2 to 3 grms. of fused borax. One half of the lead is put in the bottom of the scorifier and hollowed out; the sulphides are put into the hollow and the rest of the lead poured over them; the borax is then placed on top. The assay is then conducted in the usual way. The slag and cupel should be ground up and assayed, and the result added to the main assay."

In the following table are given: 1st, the results of plain scorification assay by this method; 2nd, the ounces per ton found in the slag and cupel; 3rd, the percentage in slag and cupel; and 4th, the total silver found by adding the slag and cupel silver to the scorification silver by one assayer; 5th, the total silver as found by another assayer

upon the same samples; and finally, the difference between the two assayers.

Ozs. per Ton by Commercial Assay. First Assayer.	Ozs. per Ton in Slag and Cupel. First Assayer.	Per Cent in Slag and Cupel. First Assayer.	Total Ozs. per Ton.		Differences.

On comparing results on individual lots considerable variation will be found between the two assayers, but on considering the total amount of silver involved the difference becomes quite small. By the first assayer these eleven lots contain 236,118.99 oz. of silver, while by the second they contain 235,483.88 oz., the difference between the two being only 54.89 oz. This amount is 0.0232 per cent. of the smallest total of ounces found and 0.0095 per cent. of the weight of sulphides involved, and shows that when carefully and properly executed the method gives concordant results on averaging a sufficient number of assays.

As showing the difference which may occur by this method of assaying, besides noting the individual difference above between the two assayers, it may be added that one of these found the following difference on assaying the same sample at different times:—

	Oz per Ton.
No. 1.....	141
No. 2.....	90
No. 3.....	112

Again, in using this method we usually start four assays of each sample. As we have found the charge rather destructive to scorifiers it is not unusual to lose an assay. In two sets of four results the differences between the highest and lowest individual results were 49.6 and 55 oz. per ton. In five sets of three results the differences were 36, 54, 94, 98, and 152.2 oz. per ton. As each one of a set of assays was carried through under practically the same conditions as the others, these differences may seem rather high, but the total ounces represented by these seven assays was 121,346.53 oz., while another, very expert assayer by this method, working upon the same samples, found 121,416.56 oz., showing a difference of only 99.93 oz. on the total number of ounces involved.

Mr. Russell has stated to the writer that in his opinion the very best assay of Russell sulphides, that can be made is still about $\frac{2}{3}$ of one per cent. below the actual amount of silver present. That there is a considerable loss of silver in assaying these sulphides, even by the above corrected method, we know by practical experience.

In the 1894 run of the Marsac refinery 116,519.5 lb. of sulphides, carrying 572,541.45 oz. of silver by the corrected assay, were refined by the sulphuric acid process invented by the writer.

Now in practical operations there must necessarily be some losses, but in this case the losses were less than the difference between the corrected assay and the amount of silver actually present, for we recovered 2,073.81 oz., or 0.36 per cent. more silver than the corrected assays called for.

In a number of cases the slag and cupel have been assayed separately, but there does not seem to be any uniformity of results, except that the cupel silver is generally much greater than the slag silver, although in one case they were both the same—0.8 oz. In a set of 29 assays running from tailings at 6.2 oz. per ton to ore at 44.7, the cupel silver varied from 0.8 to 5.4 oz per ton, and the slag silver from

0.1 to 1.8 oz. per ton; the lowest cupel silver was on 18-oz. ore and the highest on 24.1-oz. ore; the lowest slag silver was on 26-oz. ore and the highest on 32.4-oz. ore, and both these assays were made by the crucible method. In only two cases was the cupel silver less than 1 oz. per ton, and one of these was on the 6.2 oz. per ton tailings, and in only two cases was the slag silver over 1 oz. per ton.

In a recent paper on "Assays of Copper and Copper Mattes" reported to the American Institute of Mining Engineers, some interesting figures are given on this point. In assaying copper matte carrying about 55 per cent. copper and 129 oz. of silver per ton, one assayer reported 0.3 to 1.0 oz., another none to 0.35, and another none in the slag, while in the cupel the first reported 3.2 to 4.0, the second 1.0 to 2.1, and the third did not report. Again, on copper bearings carrying about 98 per cent. copper and 160 oz. of silver per ton, the same three assayers reported 0.8 to 0.35 to 1.5, and none in the slag, and the first two 4.8 to 8.7 and 2.0 to 5.5 in the cupel.

While the correction for slag and cupel loss is easily made and ought always to be made when accurate statistics are kept, there is yet the volatilisation loss to correct, and some means of doing this is desirable. While a check assay answers very well for bullion, it would hardly be possible to construct check material for the varying characters of ores and products ordinarily met with.

The question is sometimes asked if some wet method would not be better than fire assaying, but at present no such method is available for general assaying.

In the absence of copper the Volhard method of titration with sulphocyanide is highly recommended, and it has been proposed to dissolve cupriferous materials, separate the silver as bromide, reduce it to metallic silver by zinc, dissolve and titrate; but this method recovers only about 90 per cent. of the silver, and finally various scraps have to be gathered up and assayed to make up the total.

Again, it has been proposed to dissolve and precipitate the silver as AgCl , with or without a collector, generally sulphate of lead, to gather up and envelope the AgCl and then assay. While these methods may be more accurate than the uncorrected assay of such material, yet they consume much more time and finally depend upon an assay in which the slag and cupel must also be assayed if any considerable accuracy is required.

While the straight assay of any ordinary material, and especially if cupriferous or zinciferous, tends to losses by the slag and cupel, yet the removal of the foreign substances and the assaying of pure or nearly pure silver or its compounds does not avoid these losses altogether. In assaying fine silver produced at the Marsac refinery, which showed by check assays an average of 999.3 fine, the absorption by the slag and cupel was 11 oz. per thousand or 1.1 per cent. In the symposium on copper above referred to, three chemists reported slag and cupel losses in such methods ranging from nothing to 3.38 oz. per ton, while another who used a special collector reported from 4.63 to 15.0 oz. per ton of silver and 0.059 to 0.19 oz. per ton of gold.

A few words as to a common fallacy which this paper may tend to support. I think that it is pretty generally believed, particularly in the West, that the highest normal result found in any set of assays must necessarily be the best and nearest to the actual content of the material assayed, but this is by no means the case. In avoiding Seylla we may easily fall into Charybdis.

In cupelling at a low heat in order to avoid loss of silver by volatilisation we may easily leave foreign metals in our silver beads and get too high results. In the copper symposium one chemist reported from 0.3 to 1.0 oz. silver per ton in the slag, and 3.2 to 4.0 oz. silver per ton absorbed by the cupel, but at the same time he reported from 2.3 to 3.33 oz. per ton of copper left in his silver bead. Another chemist reported from 5.7 to 6.3 oz. silver per ton in his slag and cupel, but also 5.6 oz. per ton of copper in his silver button.

In the assay of Russell sulphides by the above method, notwithstanding the enormous excess of lead used—36 times the weight of sulphides taken—the final silver beads often if not always carry some copper. In six cases the amount varied from 6 to 13 oz. per ton, and averaged 9.16 oz. per ton.

ANALYSIS OF CHROME ORES.

BY ELWYN WALLER, PH.D.

RECENTLY, in examining some chrome ores, use was made of a method essentially that of Clark (J. Chem. Soc. LXIII., 1079) decomposition by sodium peroxide, &c. The recent discussion between Kidal and Rosenblum on the one side (this Journal, 1895, 1017) and Saniter on the other (*ibid.* 1896, 155) has induced me to present my own experiences.

The plan pursued may be described as follows:—

About 0.5 gm. of the finely pulverised ore was accurately weighed out in a small nickel crucible (about 3.5 cm. diameter at the top, and 3 cm. high; weight, 9 to 12 grms.). On top of this was weighed approximately 2 grms. of dry powdered sodium peroxide. The powders were mixed by means of a stout platinum wire, any material adhering to the wire being shaken or brushed back into the crucible by the aid of a feather.

The crucible was then supported on a nickel-wire triangle and a low flame applied, which, in the course of about two minutes, brought the mass into a state of quiet fusion. This heat was maintained for eight to ten minutes, and then, grasping the crucible with the tongs, and raising the flame, the mass was brought to a visible red heat, the crucible being moved about so as to give a rotary motion to its contents. This condition was kept up for a full minute, when the crucible was allowed to cool.

When the crucible was cool enough to be handled it was laid on its side in a small casserole, and 50 to 80 c.c. of boiling water added. By turning the crucible about with a glass rod the mass was soon dissolved, complete solution being marked by the cessation of effervescence. The crucible was then rinsed off with more boiling water and removed. Boiling the solution for about five minutes to decompose any remaining peroxide was the next step.

The solution was then filtered into a half-litre flask, and the black insoluble residue washed with cold water until the washings ran absolutely colourless. The contents of the flask were acidified with dilute sulphuric acid, cooled, if not already so, and the flask filled with cold water to the mark. After mixing by pouring back and forth into a beaker, the solution was titrated (in two lots of 250 c.c. each), preferably, after dilution, by use of standard hyposulphite solution containing 30 grms. of the crystals per litre—of course after adding potassium (or sodium) iodide, 15 to 20 c.c. of a 10 per cent. solution, finishing with starch in the usual manner.

Comments.—The analyses were conducted on ores ground to an impalpable powder. A side test on a portion of one ore, which was only fine enough to pass a 60-mesh sieve, made it seem probable that the method described might serve with ores coarse enough to pass a sieve of that size.

The size and shape of the crucible were found to make an appreciable difference. On using a broad dish for the fusion, imperfect decomposition of the ore was attained with the same proportions of ore and flux.

The temperature used appeared to be somewhat higher than that prescribed by Clark, since he designates a "pasty" condition, but (except at the end) was lower than that recommended by Saniter. Raising the temperature but little above that necessary to give a liquid melt, caused "spitting," resulting in loss, unless the melt was kept constantly moving as described. A higher temperature during the fusion also caused a more decided attack of the crucible.

Using a crucible of the size specified, and working as described, it was found that 2 grms. of sodium peroxide sufficed to decompose readily 0.7 to 0.75 gm. of ore when containing 35 to 50 per cent. or over of Cr_2O_3 . With lower grade ores, especially when much silica was present, the proportion of flux needed to be larger, the higher grade of ores usually decomposing the more readily. In general terms it seemed that the larger the amount of flux used over and above that necessary to decompose the ore, the more decided the attack of the crucible. A crucible weighing originally 9.7593 grms. after 18 fusions weighed 8.3149 grms., an average loss for each fusion of about 80 mgrms. The maximum loss for any one fusion was 268 mgrms., the minimum, 7 mgrms.

The usual loss in fusing at a low temperature was 20 to 50 mgrms. Some heavier crucibles lost proportionately more.

The black residue, insoluble in water, was digested warm (paper and all) with dilute sulphuric acid (1:9) for 15 or 20 minutes, when it dissolved to a clear solution, showing no black grains of undecomposed ore. It was found that when silica was to be determined, the black coating which adhered to the inside of the crucible contained some silica, and required to be dissolved off in the same manner. In any case, this treatment was applied in order to clear the crucible for subsequent use. Hydrochloric acid acted in the same way, but more rapidly than sulphuric acid.

The water solution of the melt always showed indications of the presence of some peroxide, which was apparently smaller in amount the hotter the water,—that is to say,—acidification without previous boiling afforded a coloration attributable to the formation of perchloric acid, and neutralisation with ammonia then afforded a precipitate coloured greenish by chromium hydrate. This phenomenon was more marked on acidifying with sulphuric acid than with hydrochloric. Indeed, when the melt was dissolved in cold water and sulphuric acid was added, the colour of the solution passed rapidly through dirty blue-green to the green of chromium sulphate. No intermediate colourless stage noticed by Rideal and Rosenblum was observed.

The iron method, as well as the hyposulphite titration, was tried in several cases, and concordant results were obtained. The latter method was found to be much the more convenient, and eventually was used exclusively. Dilution to at least 600 or 700 c.c. is desirable, in order to render the end reaction with starch easily discerned. This, however, is to a considerable extent a question of accustoming the eye to the tints.

The hyposulphite solution was standardised by weighing out some pure potassium dichromate which had been pulverised and then thoroughly dried in the air-bath, dissolving it in the proportion of 1 gm. (= 0.517 Cr₂O₇) in 100 c.c., and testing on four or five lots of 10 c.c. each.

For this and for many other purposes, a Müller's starch solution is the most satisfactory, in which the starch is moistened with a few drops of caustic potash (or soda) solution and then dissolved in warm water. The few drops of the starch solution were in no case added until the coloration due to free iodine had been nearly destroyed by addition of the standard hyposulphite.

The iron titration, if applied as described by Sutton (Volumetric Analysis, 6th edition, p. 154), involving as it does the weighing out of some ferrous ammonium sulphate for each titration, has obvious inconveniences, and the use of a solution of the salt, which will require frequent re-standardisation, is also much more troublesome than the hyposulphite method.

I.—PLANT, APPARATUS, AND MACHINERY.

The Concentration of Liquids [Injection of Hot Air].

R. Wirth. Chem. Zeit. 1896, 20, 306.

THE author remarks that although the process of blowing hot air through the liquid which has to be evaporated is very little used, it is extremely efficient. The pan should be set in connection with a condenser and a vacuum pump. Whilst the boiling point of the substance under treatment is lowered considerably by the partial vacuum and the rapid evaporation, the vessel does not require to be directly heated, and so wear and tear of plant are considerably reduced. The air should be broken up into a number of fine streams. When concentrating saline liquids by this arrangement, "creeping" is much reduced.—F. H. L.

Vegetable and Animal Matter, Improvements in Apparatus for Drying. A. Ludwig, London. From S. Moser, Frankfurt-on-Main, Germany. Eng. Pat. 3859, Feb. 20, 1896.

This invention relates to improvements in Ryder's apparatus for drying fruit, &c. (this Journal, 1886, 39). The furnace is enclosed in a double casing, and the air supply is drawn through an asbestos filter placed between the inner and outer casings, which both cleanses the air from dust and at the same time warms it and economises heat. Further economy is effected, and a more even temperature in the drying flues secured, by causing the hot gases from the furnace to pass into the lowest flue through a compartment filled with sand fixed along the bottom of the flue.—L. A.

II.—FUEL, GAS, AND LIGHT.

Carbon; The Combustion of, in Air. A. Naumann. Zeits. angew. Chem. 1896, 200.

ACCORDING to a series of experiments carried out by the author in conjunction with R. Ernst, the relation between the amounts of monoxide and dioxide produced during the burning of carbon in air, is strictly dependent on the temperature of combustion. The formation of dioxide begins at 400° C., and is accompanied only by small quantities of monoxide. The former rapidly increases to a maximum of 20 per cent. of the evolved gases by volume at 500°, remaining almost constant up to 700°. At 700° the production of monoxide is very small, but rises quickly at and above 800°; while at 1,000°, 34.3 per cent. is to be found in the waste gases, the highest amount theoretically possible. Provided that the air is not caused to pass too rapidly over the heated carbon, oxygen entirely disappears between 500° and 700° C., carbon dioxide being formed along with only small quantities of CO. At about 900° C. the formation of CO increases rapidly, and at 1,000° C. and over, exclusively carbon monoxide is produced, all oxygen being completely consumed.

J. Lang (Zeits. phys. Chem. 1888, 2, 178) has shown that CO₂ already formed cannot be again completely reduced by carbon to CO between 1,000° and 1,100° C. Now, since absolutely no CO₂ could be detected in the combustion products of carbon at 1,000°, above referred to, it follows that the production of that carbon monoxide must have been a direct production, and not in any wise due to reduction of CO₂.—F. H. L.

Petroleum Lamps, Diminution of the Flame in. A. G. Chem. Rev. u. d. Fett- u. Harz-Ind. 1896, [38], 73—76.

THE apparatus used in these experiments is designed by Lenoir and Forster, and consists of a glass cylinder and flat burner, the former graduated in millimetres (0—155), and provided with a tapped outlet near the base. 250 c.c. of oil are placed in the cylinder, and the wick, 20 cm. long by 24 mm. in width, having been trimmed, is lighted, the flame being adjusted to a height of 3 cm., and enough oil removed by the outlet tube to bring the level down to the mark 10.

The progressive diminution of the height of the flame can be measured by a cathetometer, or by tracing the inverted image projected on the focussing plate of a camera. The prevalence of red and yellow rays in the flame militates against the production of a good photographic image, but this difficulty is probably surmountable. Krüss's flame-measuring apparatus (Dingler's polyt. J. 283, 207) is also suitable, and the percentage of decrease may be easily calculated.

Applied to several varieties of petroleum, the method recorded considerable variation in the rates of decrease in illuminating power exhibited. The presence of acid bodies appears to be prejudicial in this respect, for at the stage when the neutral oils gave a decrease of from 25 to 34 per cent. (which may be classed as "very good" to "normal"), the light from those with an acid reaction declined to 50—64 per cent., one even falling off to the extent of 90 per cent. This latter was an oil originally of very good quality, which had been exposed to light for four months, the result being that it turned dark yellow in colour, and deposited brown resinous matter on the sides and bottom of the storage flask. Shaken up with sulphuric acid of sp. gr. 1.53, this oil turned dark red, and became black with concentrated acid. Sodium hydroxide solution (34° B.) was turned brown on being added, and the mixture separated into three layers, the central one containing the compounds of lye and acid, which, when decomposed by acids, gave an odour of petroleum acids.

The author, from personal experience, confirms the results published by Ostrejko (this Journal, 1896, 26) on the effect of the absorption of air by petroleum.—C. S.

Naphthalene in Coal-Gas, Diminution of. V. O. Keller. Gastechniker, 23, 268.

AS light petroleum has such a great power of liquefying and dissolving naphthalene, the author experimented on the introduction of crude petroleum into the carbonising retorts.

But the author concludes that the introduction of petroleum into the retorts will not obviate the stoppage of pipes by crystallised naphthalene.

Experiments were then tried with various purifiers for the same purpose. A special purifier with a glass side was employed and the gas issuing from it was led through a glass tube immersed in a freezing mixture. The following results were obtained:—

1. With the purifier empty, crystals of naphthalene appeared in the cooled tube in a few hours.
2. With the purifier partly filled with gasoline, no trace of naphthalene could be found in the cooled tube after 36 hours. The illuminating power of the gas was increased, but the flame was made smoky.
3. With lime in the purifier, a small quantity of naphthalene was found in the tube in 24 hours.
4. With Laming's mixture, no trace of naphthalene was present in the tube after 24 hours.
5. With a mixture obtained from a gasworks little troubled with deposition of naphthalene, and which consisted mainly of oxide of iron, the tube remained entirely free from naphthalene for 48 hours.
6. With a mixture of silica, 17 per cent.; alumina, 28 per cent.; oxide of iron, 35 per cent.; and soda, 20 per cent.; the tube was completely blocked with naphthalene in 6 hours.

The author concludes that the material used in the purifiers exerts a much greater influence on the amount of naphthalene in the purified gas than has been hitherto supposed.

PATENTS.

Gas [Liquid Hydrocarbon] for Lighting and Heating Purposes, New or Improved Process and Apparatus for the Manufacture of. P. Brentini, Earl's-field, London. Eng. Pat. 3354, Feb. 15, 1895.

This inventor proposes to manufacture gas, for lighting and heating purposes, by gas-ifying liquid hydrocarbons in a special manner; subsequently mixing the gas so produced with air, also in a special manner; with the result that he

obtains a gas of so permanent a character that it does not condense at comparatively low temperatures.

The apparatus described, is intended for domestic use, though the principle of the process is applicable to large installations as well; it is represented in the figure.

Hydrocarbon gas, manufactured by allowing liquid hydrocarbon (petroleum, kerosene, or benzoline, &c.) to fall drop by drop into the cast-iron retort, A, which is heated by coke or gas, in the furnace B, passes success-

sively through E (a water-washer), F (a surface condenser), and G (a tar collector), and arrives by H in a vessel, I, where it is mixed with a regulated quantity of air, and thence, by J, it passes to the bell gas-holder, K.

Hence, by L, the gas may pass, either direct to the burners or, traversing M² and M³ (layers respectively of granulated charcoal and of caustic lime placed upon coke), may be still further purified and dried, before consumption.

The supply of hydrocarbon to the retort, and that of air to the mixing chamber, are adjusted to one another and to the consumption of gas at the burners, and are regulated automatically.

The air supplied to I, is obtained from the collapsible chamber, N¹, into which it has been previously forced by the bellows, N N, themselves actuated by the small water-motor N¹, through the interposition of a lever and a pair of links, shown in the figure by dotted lines.

The speed of the water-motor depends upon the amount of water passing through its exhaust, U, and this is controlled by the tap, T, which, in turn, is opened or shut, according as the bell of K (to which it is attached by the cord, S) rises or falls, in consequence of the consumption at the burners being greater or less than the manufacture of gas by the apparatus.

The hydrocarbon is contained in the closed reservoir, D, which is connected by Q¹ to Q, a chamber containing a float valve which closes as soon as the desired level of hydrocarbon in the next vessel, R, has been attained. From R, hydrocarbon passes by C to the retort A.

The gas spaces of Q and R are in communication; and those of D and R are in connection with N¹. The faster the water-motor works, and the greater the pressures produced in N¹, D, and R, the larger will be the quantity of hydrocarbon supplied to the retort, and the larger also the quantity of air to the now greater quantity of gas manufactured; the ratio of gas to air remaining, however, constant.

The object of the constant level of hydrocarbon in R, is to secure the sole dependence of the supply to the retort, upon the amount of gas pressure existing, from time to time, without influence from the height of liquid in R.

By slight additions to the apparatus, the supplies of water to the condensers, and of gas for heating the retort, may be similarly controlled automatically, so as to accord with the consumption of gas at the burners.—E. R. B.

Illuminating Gas [Oil], Improvements in the Manufacture of. A. R. Newman, London, and J. M. Somerville, Grove Park, Kent. Eng. Pat. 8746, May 2, 1895.

The apparatus proposed by these inventors comprises, (1) a retort, made up of inclined metal cylinders, arranged in zig-zag order, and set across a chamber, through which pass the waste blast gases, from a water-gas producer, and (2) a fixing-retort, which is a vertical metal cylinder, of elliptical section, and made up of three lengths, suitably jointed together. The interior of the fixing-retort is largely occupied by a considerable number of gratings, placed one above the other, at a short distance apart; the bars of the gratings being arranged at different angles, so that the gases, in ascending the retort, traverse a spiral path, and acquire a gyratory motion; the action of heat upon the gases is thus greatly increased, by reason of the increased heating surface to which they are exposed. The plant also includes (3) a pair of water-gas producers, worked alternately in the usual way.

In working the apparatus, oil descends from a suitably placed tank, through a pipe placed in the heated wall of the retort chamber. The oil, the temperature of which is now raised nearly to the boiling point, flows into the uppermost part of the zig-zag retort and traverses it, in company with the water-gas; the mixed gases subsequently ascending the fixing-retort, and such reactions ensuing from the heating, that a permanent gas is obtained.

The oil which is to be employed with the apparatus, is not specified by the patentees.

The steam employed is superheated by passing it through a coil, placed in the path of the waste blast gases; and the air, made use of to effect the complete combustion of the blast gases, and which is admitted on two successive occasions in the cycle of manufacture, is highly heated, by virtue of traversing channels in the heated walls.

The fixing-retort is also heated by the waste blast gases; for it is enclosed in a jacket, through which the waste gases pass on their way to the chimney.—E. R. B.

Incandescence Gas Lights, Improved Illuminating Appliances for. J. Moeller, London. Eng. Pat. 2224, Jan. 31, 1895.

IN place of the ordinary fabric forming the groundwork for the deposition of the earthy oxides, used in the preparation of incandescent mantles, which is liable to unequal shrinkage, thus constituting a source of weakness in the finished mantle, the inventor proposes to substitute a material composed of independent rings, linking one into the other, but not otherwise attached, and therefore not subject to the strains arising from unequal contraction. The links may be made of pieces of suitable thread, knotted after being looped together.—C. S.

Incandescent Carburetted Air or Gas Lighting, Improvements in, and Apparatus therefor or connected therewith. D. Hancock, J. B. Craig, and A. H. Hancock, all of Stratford, London. Eng. Pat. 3424, Feb. 16, 1895.

THIS patent relates, more especially, to the various modes of burning a certain carburetted air or gas, the manufacture of which is described in the specification in application for Patent 3425 of 1895 (see following abstract). The burners now described are "non-atmospheric," in the sense that the mixture of gases consumed at them contains already sufficient oxygen for complete combustion.

All the forms described are *pendent* burners, and, in all of them, the gaseous mixture is conducted into a box or chamber, which is attached to the downwardly directed gas tube; and, in two of the modifications of the burners, the gas escapes from the box into the interior of a mass of material (not otherwise specified), and, by its flame, renders it incandescent. In a third modification, the flame externally heats a conical mass of incandescing material, enclosed in a wire cage.—E. R. B.

Carburetted [Air] Apparatus, Improvements in. D. Hancock, J. Bell, and A. H. Hancock, all of London. Eng. Pat. 3425, Feb. 16, 1895.

THIS invention consists of an apparatus for forcing warmed air through mineral oils or spirits in order to produce an inflammable gas.—R. B. P.

Incandescent Lighting, Improved Method of combining Air and Gas. H. Gardner, London. From La Société Française de l'Héliogène, Paris. Eng. Pat. 11,820, June 18, 1895.

IT is proposed in this invention, in order to increase the illuminating power of ordinary flat-flame gas-burners, to force air by a blower (or other means) into the gas pipe in such a manner as to produce a mixture of 3 parts of air to 1 of gas at a pressure of 15 to 20 mm. water gauge. The jet, which burns with a blue oxidising flame, impinges on a fringe of radiant material suspended above the burner, and heats the said fringe to incandescence, producing thereby a brilliant light.—C. S.

Incandescence Spirit Lamps, New or Improved Gasifying Apparatus for. G. Tresseureuter, Berlin. Eng. Pat. 1162, Jan. 16, 1896.

THE apparatus described, which is intended for domestic use, is intended solely for the production of spirit vapour.

The apparatus comprises a vertical axially disposed tube, containing a wick, and leading, at its lower end, into a reservoir filled with spirit, and at its upper end to the burner. Around this upper end is another chamber, into which spirit may be introduced by means of a small pump;

the latter being a part of the apparatus which, though concealed within the reservoir, is operated from the outside by a small lever handle.

In working the apparatus, the spirit in the upper chamber is lit, whereupon the axial tube is warmed, and the spirit brought up by the wick, vaporised. Some of the spirit vapour so produced, passes direct to the burner, and some to a small injector; the latter supply, mixed with air, which is sucked in at the injector, is conveyed by a tube, to a perforated annular tube encircling the wick tube in the upper chamber. Through the apertures of the annulus, the spirit and air mixture escapes, inflames, and carries on the warming of the wick tube which was commenced by the spirit pumped into the upper chamber.

The injector and its principal parts, except the air-holes, are enclosed within the upper chamber.

The apparatus is so constructed that air-spaces are provided between the wick tube and the contents of the lower chamber, and also between the upper and lower vessels, so as to minimise, as far as possible, the effects of radiated or conducted heat upon the contents of the lower chamber.—E. R. B.

Water-Gas from Coke, Coal, or other Fuel, Improved Process of, and Apparatus for the Generation of. H. Strache, Vienna. Eng. Pat. 3487, Feb. 18, 1895.

TO generate water-gas from coal, &c., the air required for combustion during the admission period is heated by means of the hot combustible gases from the regenerator, aided by a "recuperator."

During the gasifying period, steam is superheated in the regenerator, and utilised for coking the fuel. The resulting gas and vapours pass, along with steam, through a highly heated column of coked fuel, and are converted into water-gas.

The generator consists of a vertical cylindrical chamber, the top part of which is occupied by the fuel to be coked, whilst in the lower part is the hot coked fuel.

The regenerator is filled with refractory blocks exposing a large surface, and is surrounded by an annular chamber forming the recuperator. In this there are a series of hollow, ribbed, cast-steel bodies, which form a continuous passage, surrounded outside by the hot gases from the regenerator. The air to be heated is passed through this passage.—R. B. P.

Gas [Air Gas], Improvements relating to the Manufacture of, and to Apparatus therefor. J. H. Ladd, London. Eng. Pat. 10,477, May 27, 1895.

(IMPROVEMENTS ON Stringfellow's patent. This Journal, 1891, 453.) Stringfellow obtained a combustible gas by passing air over screens impregnated with liquid hydrocarbons and subsequently over screens moistened with water, so that moisture might be taken up. The patentee proposes, when necessary, to employ heat either by previously heating the air, the hydrocarbon, or the water, or any two of them or all three.—L. T. T.

Smoke, Purification of; and the Recovery of Soot from the Products of Furnaces, Improvements in or relating to. G. Mugna, Budrio, Italy. Eng. Pat. 5834, March 20, 1895.

See under XVIII. B., page 466.

Acetylene Generating and Storing Apparatus, Improvements in. E. Gearing, Harrogate. Eng. Pat. 6777, April 2, 1895.

THE metallic carbide is contained in a generating vessel closed by a water-luted cover. The carbide is placed in a perforated vessel which can be lifted in and out of the generator, thus facilitating charging and discharging.

Water is admitted as a spray on the top of the carbide. The acetylene generated, passes through an intermediate chamber, forming a water lute, into a gas-holder of ordinary construction, the rising and falling of which regulates the amount of water admitted into the generator.

—R. B. P.

Acetylene, Improvements in Apparatus for Use in the Production and Utilisation of. E. Ducretet and L. Lajeune, both of Paris. Eng. Pat. 16,502, Sept. 3, 1895.

APPARATUS for the production of acetylene, by the decomposition of calcium carbide with water, is described by the inventors, who state that their apparatus differs entirely from those heretofore known, "in which the pressure of the acetylene gas removes the liquid from the carbide of calcium, but does not prevent its contact with water vapour, whereby slow, but continuous, decomposition can take place, with consequent danger and loss of the acetylene gas, apparatus of this kind not being capable of storing it at the high pressure which is produced by its evolution."

In the apparatus of the inventors the gas is produced, and if necessary stored, at any ordinary pressure which may have been previously agreed upon.

The apparatus consists of two stoutly constructed vessels, fitted to withstand considerable pressure, the upper one (which contains water) being in communication with the lower one (which holds the calcium carbide) by two tubes, one of which puts the gas spaces of the vessels into communication, while the other allows water to flow from the upper vessel into the lower one.

In the upper part of the lower vessel there is a valve-like structure, the piston of which is expelled by such pressures as may overcome a spring on the other side of this piston; the spring may be tightened up by a screw workable from the exterior of the apparatus, and, as the lower vessel is also provided with a pressure gauge, the valve may be adjusted so as to operate at any pressure which the acetylene, accumulating in the lower vessel, may have set up.

In retreating, the piston permits another spring to bring a plug against the aperture by which water is entering the lower vessel.

A portable lamp, and several other modifications, are also described.—E. R. B.

Acetylene Gas, for Acetylene Gas Lighting, Improved Process and Apparatus for the Production of. F. Rossbach-Rousset, Tempelhof, near Berlin. Eng. Pat. 1116, Jan. 16, 1896.

This inventor obtains acetylene by the decomposition of calcium carbide with water, the present invention providing

means for the regulation of the water supplied to the carbide, such means being dependent upon the pressure of the gas produced by the reaction.

The vessel containing the calcium carbide is enclosed in a gas-tight chamber, and the water-supply pipe traverses this chamber, is bent into a U outside the chamber, and then re-enters it, ending immediately over the calcium carbide vessel, into which it can therefore discharge its contents.

When water flows into the calcium carbide, and, in consequence, acetylene is generated, the pressure of the gas tends to check the influx of water; on the other hand, owing to the heat of the reaction, water, in the limb of the water-supply pipe, which, as stated above, traverses the chamber, is converted into steam, and the pressure so set up tends to neutralise that set up by the gas.

In a further modification of the apparatus, gas flames are applied to heat the water-supply tube.—E. R. B.

Gases, Specific Gravity of; Apparatus for Ascertaining. A. Custodis, Düsseldorf, Germany. Eng. Pat. 7791, April 18, 1895.

See under XXIII., page 472.

Gases, Weight of; Apparatus for Indicating and Registering. M. Arndt, Aix-la-Chapelle. Eng. Pat. 8615, May 1, 1895.

Gas Furnaces, Regenerative; Improvements in Devices for Reversing the Directions of Flow of Gas or Air in. J. R. Wright and W. Veitch, both of Gowerton. Eng. Pat. 9311, May 10, 1895.

The figure shows the apparatus of the inventors, in vertical section, and, in it, E is the inlet for gas or air, D communicates with the chimney, and C and C' with two regenerators. A is the valve proper, and it is represented as connecting C to D. It may, however, be moved so as to connect C' with D, the mechanism for this purpose being two weighted levers, J J, linked together by j, and attached to short shafts, i i. The shafts lie in bearings in the wall of the casing, B, and their inside ends are connected by cranks, h h, to the brackets, a u, of the valve, A.

The recesses, F F, contain luting material. Of the valve A, the inventors state that it "gives an opening through it of the full area of the flues, and is not injuriously affected by heat or flame, or its operation impeded by tar or soot." In the event of leakage, the valve proper need not be removed, but the leakage can be repaired, by unskilled persons, even when the furnace is in work.—E. R. B.

Gas, Sampling for Analysis; Improvements in Apparatus for. B. L. de Ridder, Amsterdam. Eng. Pat. 10,905, June 1, 1895.

See under XXIII., page 472.

Vaporizing Burner for Oil, Improved. J. Barany and J. Mücke, Berlin. Eng. Pat. 11,767, June 17, 1895.

THE main feature of this apparatus consists in a seal of fusible metal into which dips an inverted bell containing the liquid to be vaporised. The metal fuses at a higher temperature than is required to gasify the heaviest constituents of the liquid, and in its molten state allows the gas to escape from the bell into the surrounding chamber, whence it is conducted to a Bunsen or illuminating burner in the ordinary way. When the source of heat is removed, the metal solidifies and prevents the escape of any further amount of vapour. The supply to the burner is regulated by a screw valve attached to a diaphragm.—C. S.

Gases of Easily Inflammable Liquids, Gasifying and Increasing the Heating Power of the. E. Rohrbach, Berlin. Eng. Pat. 15,890, Aug. 23, 1895.

IN this apparatus the two ends of a bent horse-shoe-shaped pipe dip into the oil in the main reservoir. At the upper end of the horse-shoe pipe another pipe goes to the burner. From this latter pipe, a small metal pipe branches off, coils round the said pipe and rejoins it. From the coiled pipe, however, a capillary tube also leads downwards to below the coils, thus carrying some of the vapour, which, when ignited, heats the coiled and main tube and continues the gasification. The initial gasification must be effected by an external source of heat.—L. T. T.

Furnaces, Improvements in. A. M. Hewlett, Kewance, Ill., U.S.A. Eng. Pat. 16,297, Aug. 30, 1895.

See under X., page 458.

Gas Furnaces, Regenerative: Improvements in and connected with. A. Müller, Berlin. Eng. Pat. 19,355, Oct. 15, 1895.

THIS consists in using a coke fire, fed from the top, with flues for taking off the generator gases about one third or fourth of the height of the fuel chamber above the fire-bars. In this way the patentee claims a constant height of incandescent material, and, by properly arranging draughts, the obtaining of his generator gas as carbonic oxide and nitrogen, almost free from oxygen or carbonic acid. By using short flues and admitting previously heated air immediately at the end of these flues, the patentee claims perfect combustion with great saving of heat, and in the chimney gas almost solely carbonic anhydride and nitrogen, so that where carbonic anhydride is to be recovered there is still further economy.—L. T. T.

Coke Furnaces or Ovens, Improvements in. H. Stienes, Muhlheim-on-the-Ruhr, Germany. Eng. Pat. 24,823, Dec. 27, 1895.

THE heating of the furnace is effected either by the gases generated during the coking process, or, if it be desired to utilise these for other purposes, by gas from separate generators.

The furnace is constructed with two systems of heating flues, both being divided into halves at the middle of the length of the furnace by a wall, whilst the coking chamber runs the whole length.

The furnace is so built that those parts subject to most wear can be repaired without seriously disturbing the adjoining parts.—R. B. P.

Petroleum, Spirit, and Analogous Liquids, Improvements in Apparatus for Gasifying. D. Young, London. From F. H. Aschner, Berlin. Eng. Pat. 1648, Jan. 23, 1896.

THIS consists in a gasifying apparatus for combustible fluids, in which a collecting chamber is interposed between the gasifying chamber and the burning-nozzle, from which collecting chamber there is a passage controlled by a suitable valve, and provided with one branch leading to the burner-nozzle, and another branch, suitably controlled, terminating in a burner placed below the gasifying chamber. Below this latter is a small pan for the warming-up liquid. When the gasification is once started by burning combustible liquid in the above-mentioned pan, it is continued by means of a part of the gasified material passing down the

branch pipe to the heating burner below the gasifying chamber. The petroleum, spirit, or other combustible is drawn from the main receptacle to the gasifying chamber by means of a wick.—L. T. T.

Hydrocarbon Furnaces, Automatic Re-ignition Apparatus for. S. Pitt, Sutton, Surrey. From La Compagnie Internationale des Procédés Adolphe Scigle, Paris. Eng. Pat. 5409, March 10, 1895.

IN the path of the flame, between the sprayer or gasifier and the furnace, is interposed a hollow metal cylinder perforated with air-holes and lined with non-conducting material, and containing a second smaller cylinder or truncated cone which, heated by the flame, remains red hot for several moments after the latter has been extinguished, and automatically re-ignites the jet in case it is put out.—C. S.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Petroleum, Italian. C. Flaumet. *Moniteur des Produits Chimiques*, 1895, 25, [18].

THE most important oil-bearing districts in Italy are Montanaro di Piacenza, Rivanozzano, near Voghera, Zocca-Casauria, and San-Giovanni-Incarico. Montanaro oil has a specific gravity of 0.7849 at 15° C., and yields 44.7 per cent. of light oil, 19.8 per cent. of a slightly heavier grade used for naphtha lamps, 22 per cent. of kerosene, and 14.4 per cent. of lubricating oil. The crude oil is free from H₂S. Rivanozzano oil has a specific gravity of 0.9132, and yields correspondingly heavier distillates. Zocca-Casauria oil is bituminous, having a specific gravity of 0.951. About 33 per cent. of burning oil and a good deal of black residuum suitable for varnish making is obtained from it. San-Giovanni-Incarico oil is a bitumen of sp. gr. 0.974, and containing much sulphur. A burning oil of sp. gr. 0.921 and flashing point of 85° C. can be obtained from it.—B. I.

Petroleum Products, Action of, on Aluminium. K. W. Charitschkow. *Trudy kak. otd. imp. russk. tekhn. obschutseh*, 1896, 11, I. 16.

STRIPS of pure aluminium were almost completely immersed in the distillates from petroleum, solar oil, and benzene, and in petroleum spent acids for four months at the ordinary temperatures. With the exception of that exposed to the action of benzene, which had increased in weight 0.08 per cent. and become slightly spotted, none of the strips were acted upon. The author suggests the lower molecular weight of benzene as the possible explanation of its greater energy. At temperatures of 75°–80° C. and 100°–120° C., the strips in the petroleum distillate and crude petroleum were intact after 48 hours, but after heating at 175°–180° C. for 38 hours under a reflux condenser, the aluminium in each case had increased in weight—in the petroleum distillate by 0.016 per cent. and in the petroleum by 0.017 per cent. From these results the author considers pure aluminium superior to copper and equal to iron, in its power of resisting the action of petroleum. It is specially suitable for vessels, such as cooling tanks, &c., in which the temperature of the petroleum does not exceed 120° C. Obviously the oil must be freed from any alkali, which would increase its solvent power.—C. A. M.

Cyclopentadiene in Coal Tar, the Indene of the Fatty Series. G. Kraemer and A. Spilker. *Ber.* 1896, 29, 552–561.

SOME time ago (this Journal, 1891, 38) the authors, in describing the isolation of Indene and Fluorene from coal tar, referred to a third hydrocarbon of the formula—

which they were hopeful of finding in the lowest boiling fractions of coal-tar oils. When subsequently Etard and Lambert extracted from compressed gas oils a product having the formula C₉H₈, named propetylene, the authors expressed the opinion that it must be the simplest form of

Indene. The first runnings from crude benzene or compressed gas oil formed the raw material for the present investigation. It was soon observed that prolonged standing affected the boiling points of these oils in an upward direction. Careful fractionation of the light oils thus changed, yielded a liquid boiling at 160° – 175° , from which the monomolecular hydrocarbon, named Cyclopentadiene by the authors, was isolated. It boils at 41° (corr.) under 760 mm. pressure, sp. gr. 0.815 at 15° – 15° ; it is insoluble in water, but miscible in every proportion with alcohol, ether, and benzene. Concentrated sulphuric acid and nitric acid cause it to explode; dilute acids and alkalis resinify it. It reduces an ammoniacal silver solution containing potash. Mono-, tri-, and tetrachloro compounds are described.

Dibromocyclopentene is obtained by combining Cyclopentadiene, suspended in twice its weight of light petroleum, with the theoretical quantity of bromine at -15° to -20° . It forms colourless crystals melting at 45° to 46° , is readily soluble in alcohol and chloroform, but decomposes *per se* or when treated with alcohol and water. Tetrabromocyclopentane is also described.

The authors maintain that the results they obtained on chlorination and bromination, confirm the correctness of the formula originally assigned by them to Cyclopentadiene, the discovery of which fills up a gap in the Indene series, thus:—

Trimethylbenzene, Consecutive, Accompanying Synthetical Mesitylene. A. Lucas. Ber. 1896, 29, 953–958.

THE author is in a position to assert that mesitylene, even when obtained from the purest acetone by synthesis, always contains hemellitrol (consecutive trimethylbenzene) in appreciable quantity, but the presence of pseudocumene could not be detected.—D. B.

Chrysoketone, Synthesis of, and Constitution of Chrysene. C. Graebe. Ber. 1896, 29, 826–828.

THE ready formation of fluorenone from ortho-amino-benzophenone induced the author to resume his studies on the constitution of chrysene. By reason of the pyrogenic synthesis of chrysfluorene from β -benzyl-naphthalene, the suggestion seemed probable that this hydrocarbon and consequently chrysene, is a 2,3-derivative of naphthalene. Commencing with oaphthylbenzoic acid, the author, in conjunction with Schestakow, attempted the synthesis of chrysoketone according to the following formula:—

The resulting compound was identical with the chrysoketone described by Bamberger and Kranzfeld. It is further shown that the acid obtained from naphthalene and phthalic anhydride is an α -derivative, namely, 1 naphthyl-phenylketone-2'-carboxylic acid.

From these results, the author concludes that chrysfluorene—or naphthofluorene, as he prefers to call it—and chrysene are 1-, 2-derivatives of naphthalene.—D. B.

Paraffin, Pine Resin in: Detection and Determination of. J. Klimont. Chem. Rev. u. d. Fett- u. Harzind. 1896, [38], 76–77.

See under XXIII., page 475.

IV.—COLOURING MATTERS AND DYES.

Luteolin. J. Herzig. Ber. 29, 1896, 1013–1014.

THE author calls attention to some points suggested by the work of A. G. Perkin on luteolin, the principle found in the yellow dyestuff *weld*. J. Chem. Soc. Trans. 1896, 206. With reference to the action of alkalis on luteolin, Perkin has confirmed the presence of pyrocatechuic acid in the decomposition products, but was unable to discover any trace of phloroglucol. The author, on the other hand, maintains that he has observed the phloroglucol reaction, and if this observation be proved to be correct, then the supposed close relationship of luteolin to fisetin will no longer hold good. See further, A. G. Perkin, Proc. Chem. Soc. 1896, [165], 105.—J. S.

Thio-Aldolaniline and Aldehyde Green. W. v. Miller and J. Plöchl. Ber. 29, 59–61.

IN the formation of aldehyde green from *p*-rosaniline by the action of *p*-aldehyde and sulphuric acid, one amido group forms the quinoline ring, whilst the other two form aldol groups containing the group :C:N, and this readily forms additive compounds. When aldolaniline—

is warmed on the water-bath with crystallised ammonium sulphide in absolute alcohol, a condensation product is obtained having the formula—

This substance, which melts at 92° C., is white, but after some time turns yellow. It is very easily soluble in ether, alcohol, and benzene, but is almost insoluble in petroleum ether. It is probable that the sulphur in Aldehyde green has a somewhat similar position, the formula of that containing two atoms of sulphur probably being—

and the formula previously given should be modified.

—T. A. L.

Naphthazarin, New Process for the Preparation of.

Ch. Gassmann. Bull. Soc. Ind. de Mulhouse, 1896, 77.

TEN kilos. of 1,5-dinitronaphthalene are dissolved in 100 kilos. of monohydrated sulphuric acid, and to this solution 80 kilos. of fuming sulphuric acid (25 per cent. SO₃) and 5 kilos. of perfectly dry infusorial earth (Kieselguhr) are subsequently added. This mixture is allowed to stand for 12 hours, and is then heated for a short time on the water-bath to complete the reaction. The whole is now poured into 500 kilos. of water, boiled, and the precipitate obtained, filtered from the cooled solution. The residue on the filter is washed free from sulphuric acid, redissolved in a solution of 15 kilos. of caustic soda of 40° B. in 50 litres of water, and the solution is run into one of 8 kilos. of sulphurous acid in 100 litres of water. The naphthazarin is precipitated, filtered, and preserved in the state of a paste. This dyestuff (naphthazarin) is largely used in dyeing chromed wool, or in the state of bisulphite.—C. O. W.

Quinoline and Quinoline Derivatives, An Improvement in Skrap's Process for the Preparation of. C. A. Kneppel. Ber. 29, 1896, 703–709.

QUINOLINE and its derivatives are at present almost exclusively prepared by Skrap's well-known synthesis, in which the nitro compound (usually nitrobenzene) acts primarily as the oxidising agent. In the preparation of quinoline itself by this method a very good yield is obtained, but in the case of nitroquinolines the yield is often small, owing to the formation of resinous substances. Skrap himself has remarked that the yield is smaller the higher the molecular weight.

The author is of opinion that the formation of resin is due to the presence of the nitro compound, and he therefore recommends the use of an inorganic oxidising agent in the shape of arsenic acid (meta-arsenic acid or arsenic pentoxide) which gives in most cases a very good yield.

For the preparation of quinoline, 76 grms. of arsenic acid, 145 grms. of concentrated sulphuric acid, 155 grms. of glycerin, and 50 grms. of aniline are heated on a sand-bath in a flask, connected with a reflux condenser until the reaction sets in. After the reaction is over the contents are kept gently boiling for 2½ hours. The liquid is then diluted with water, excess of caustic soda added, and the quinoline, together with the unattacked aniline, is distilled off in a current of steam. Sodium nitrite is now added to the distillate, mixed with excess of hydrochloric acid until the smell of nitrous acid becomes permanent, even after shaking, when the liquid is boiled to destroy all the diazo-benzene hydrochloride. Finally, excess of caustic soda is added and the quinoline distilled over with steam and extracted from the distillate with ether. The yield is 46 grms. According to Skraup, 50 grms. of aniline and 32 grms. of nitrobenzene give 55 grms. of quinoline. 32 grms. of nitrobenzene thus only increase the yield by about 7 grms. The author further describes the preparation of orthotoluquinoline, orthonitroquinoline, paranitroquinoline, paradimethylamidoquinoline, metanitroquinoline, metadimethylamidoquinoline, paraquinoline sulphonic acid, β -naphthoquinoline, β -anthraquinoline, and 1-dioxy- β -anthraquinoline ("Alizarin blue").—J. S.

Morin. Part I. B. Bablich and A. G. Perkin.

Proc. Chem. Soc. 1896, [165], 106–107.

THE yellow colouring matter, morin, exists, as has been known for some time, in old fustic (*Morus tinctoria*), and has lately been shown by one of the authors and F. Cope (this Journal, 1895, 1041) to be also contained in the Indian dyestuff, jackwood (*Artocarpus integrifolia*). By means of its compounds with mineral acids the true formula of morin was established by one of the authors and L. Pate (this Journal, 1895, 745) to be $C_{15}H_{10}O_7$.

The principal reactions of morin described by previous workers are its behaviour towards alkaline reducing agents (Hlasiwetz and Pfandler, *Jahresb.* 1864, 527), by which means it yields phloroglucol and β -resorcylic acid, and towards fused alkali, when it gives phloroglucol and resorcinol.

The results of the authors demonstrate a close similarity between quercetin and morin. Quercetin yields with fused alkali phloroglucol and protocathecinic acid, morin, phloroglucol and β -resorcylic acid.

The formula of quercetin appears to be (Herzig, *Ber.* 1895, 28, 293)—

and it seems most probable that the formula of morin is represented by that of quercetin, in which the catechol nucleus has been displaced by a resorcinol group, thus—

PATENTS.

Colouring Matters [Reds and Violets], Improvements in and relating to the Manufacture of. H. H. Lake, London. From Farbwerk Mühlheim a. M., Germany. Eng. Pat. 10,669, May 29, 1895.

THE invention is that of a new ethylamidonaphthol sulphonic acid, which combines with diazo or tetrazo

compounds to form valuable colouring matters. On sulphonating ethyl- β -naphthylamine hydrochloride in three times its weight of sulphuric acid monohydrate by adding 20 per cent. anhydride at 40° C., a mixture of isomeric sulphonic acids is obtained, the sodium salt of one of them, termed A, being soluble in cold spirit. When the sulphonation takes place at 140° C. with monohydrate only, another sulphonic acid is obtained, termed B, which is also sparingly soluble in water. When these acids are further sulphonated with five times their weight of 20 per cent. anhydride, a disulphonic acid is obtained, which is easily soluble in water, and in an alkaline solution has a bluish-green fluorescence. When heated with caustic potash at 200° C. in aqueous solution, it is converted into 3.1'.3'-ethylamidonaphthol sulphonic acid, which can be separated by acidifying a tolerably concentrated alkaline solution. The new compound, when combined with diazo-azo derivatives, gives cotton colouring matters, and can also, of course, be combined with tetrazo compounds, the dyestuffs being characterised by great purity of shade. For instance, aniline is diazotised and combined with α -naphthylamine hydrochloride. When the combination is complete, after about 12 hours, the benzene-azo- α -naphthylamine hydrochloride is further diazotised by means of sodium nitrite in an acid solution, and the diazo solution, after filtering, is run into the calculated quantity of ethylamidonaphthol sulphonic acid kept alkaline with sodium carbonate. The violet colouring matter separates at once, and is best kept as a paste. Amido-azobenzene sulphonic acid, when diazotised and combined with the new compound, gives a red colouring matter, which is salted out from the hot solution.

—T. A. L.

Azo Dyestuffs [Violet and Blue-Blacks], The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 11,228, June 7, 1895.

THESE colouring matters are derived from acidyl derivatives of *m*-diamines, capable of being combined with diazo and tetrazo compounds (*cf.* Eng. Pat. 10,668 of 1895; this Journal, 1896, 351). Such acidyl diamines are acetyl-*m*-phenylene diamine, acetyl-*m*-tolylene diamine, *m*-amido-phenylene, and *m*-amidotolylene oxamic acid. The following is a typical example resulting in the formation of a violet-black colouring matter. The diazo solution from 14.3 kilos. of α -naphthylamine is run into a solution of 18 kilos. of *m*-amidophenylene oxamic acid containing a small quantity of caustic soda lye, and an excess of sodium acetate. After agitating for 24 hours the mixture is made alkaline and raised to 50° C. The amido-azo compound formed, is then filtered off, mixed with a small quantity of water, 7 kilos. of sodium nitrite, and sufficient hydrochloric acid at about 5°–10° C. The diazotisation is complete in about 12 hours, and after filtering off the diazo compound it is added to an alkaline solution of 22.4 kilos. of 1.4'-naphthol sulphonic acid. The combination requires about 12 hours, when the mixture is heated to 50° C. and the dyestuff salted out, filter-pressed and dried. It gives violet-black shades on wool, which, after treatment with potassium bichromate, are fast to washing and fulling. The production is also claimed of the simple azo dyes obtained by combining the diazo compounds of the amidophenylene oxamic acids, their homologues and analogues, with the usual dyestuff components. Certain of the compounds derived from tetrazo derivatives and two molecular proportions of an acidyl diamine, when dyed, can be diazotised and further combined on the fibre. In all cases dark shades are obtained.—T. A. L.

Dyestuffs [Blacks and Blues] suitable for Dyeing Cotton, The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 11,276, June 8, 1895.

By the action of alkaline sulphides on 1.1' or 1.4'-dinitronaphthalene, or tri- or tetranitronaphthalenes, certain dinitronaphthalene sulphonic acids or certain dinitrohalogen naphthalene derivatives, products are obtained

which may either be used directly as dyestuffs or may be further converted by the action of acids. These latter products in their turn can undergo a further change by the further action of alkalis, alkaline sulphides, sulphites, &c. Two kilos. of 1,1'-dinitronaphthalene are added to 8 kilos of sodium sulphide fused in an oil-bath. A violent reaction sets in, the melt being subsequently heated until it has become homogeneous. After cooling, it is dissolved in water, filtered, and evaporated to dryness. Unmordanted cotton is dyed from a cold concentrated solution of the dyestuff, a deep black shade fast to acids, alkalis, light, washing, and fulling. By using a much larger proportion of sulphide (12:1) and heating until a dark-bluish homogeneous liquid is obtained, a dyestuff is produced which, when employed in a similar manner, gives blue shades. By heating these and similar dyestuffs with acids, products are obtained which dye unmordanted cotton black from hot alkaline baths containing oxidisable substances, such as grape sugar, glycerin, or the like. When treated with alkalis, alkaline sulphides, sulphites, or bisulphites, the products may be used for dyeing unmordanted cotton directly. The following example illustrates these two methods:—One kilo. of finely powdered 7-trinitronaphthalene (1,4,1') in 150 litres of water, is boiled with 12 kilos. of crystallised sodium sulphide until dissolved, when the solution is filtered and mixed with 10 kilos. of concentrated hydrochloric acid, which throws down a greyish-black precipitate. After heating the acid mixture for some time, the liquid is allowed to cool, and the intermediate compound, which forms a bluish-black mass, is filtered off. It may be used directly for dyeing purposes, giving black shades on unmordanted cotton when dyed from a hot alkaline bath in presence of oxidisable substances such as grape sugar or glycerin, or it may be converted into a colouring matter giving similar shades from a cold bath by treatment with alkalis, alkaline sulphides, sulphites, or bisulphites, when it is used preferably as a paste.—T. A. L.

Chemical Compounds [Stable Diazo Salts] suitable for the Production of Colouring Matters in Bulk or on Fibre, The Manufacture of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 11,557, June 17, 1895.

THIS is an extension of Eng. Pat. 8989 of 1895 (this Journal, 1896, 349), referring to the production of so-called tetrazo salts. According to the present invention, not only do the β -naphthol trisulphonic acids and their salts give sparingly soluble tetrazo salts, but this property is also shared by 2,1-naphthol sulphonic acid and its salts. In addition, the patentees have also discovered that the diazo compounds of nitramines, such as nitraniline, also give stable sparingly soluble salts with β -naphthol trisulphonic acid or with 2,1-naphthol sulphonic acid, and these compounds they term diazo salts. As an example of the preparation of one of these latter, a solution of 24.6 kilos. of 2,1-naphthol sodium sulphionate is run into the diazo solution from 13.8 kilos. of *p*-nitraniline and 7 kilos. of sodium nitrite in presence of hydrochloric acid. The diazo salt separates as an orange-yellow precipitate, having probably the formula $O_2N.C_6H_4.N=N.SO_3Na.C_{10}H_6O$. It is filter-pressed and may be used for combinations in place of *p*-nitrodiazobenzene chloride.—T. A. L.

Dyestuffs [Safranines], The Manufacture or Production of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 11,843, June 18, 1895.

THESE dyestuffs, which are identical with those obtained according to Eng. Pat. 9610 of 1894 (this Journal, 1895, 478), are obtained by the oxidation of a molecular proportion of a *p*-amido-alkylaniline (such as *p*-amidomethyl- or ethylaniline) together with two molecular proportions of *o*-toluidine and a mixture of equimolecular proportions of *o*-toluidine and a primary aromatic amine, such as aniline, xylidine, or the like. These alkyl-tolu-phenosafranines can also be produced by the oxidation of a mixture of equi-

molecular proportions of *p*-tolylenediamine and an alkylaniline (methyl- or ethylaniline) and a molecular proportion of a primary aromatic amine. The same products can also be obtained by other methods employed for the production of safranines; for instance, by condensing one molecular proportion of a nitroso-alkylaniline with two molecular proportions of *o*-toluidine, or a mixture of equimolecular proportions of *o*-toluidine and another primary base, or else by the reaction of equimolecular proportions of quionedi-chlorodi-imide, an alkylaniline, and *o*-toluidine, or by the action of toluquinonedichlorodi-imide on an alkylaniline and any primary amine.

An aqueous solution containing 19.4 kilos. of *p*-tolylene-diamine hydrochloride and 16 kilos. of ethylaniline hydrochloride has added to it as a 5 per cent. solution, 20 kilos. of potassium bichromate and a small quantity of acetic acid. When the formation of the indamine is complete, 13 kilos. of aniline hydrochloride in solution are added, and afterwards the same quantity of potassium bichromate as above. The mixture is gently heated on the water-bath, and the safranine, which is separated in the usual manner, dyes tanned cotton bright red. The same colouring matter can be obtained as follows:—An alcoholic solution of 17.2 kilos. of nitrosomethylaniline hydrochloride and 22 kilos. of *o*-toluidine is heated on the water-bath until a pure red solution is obtained. A small quantity of acetic acid is then added, and 20 kilos. of potassium bichromate as a 5 per cent. solution. After the reaction has ceased, the alcohol is distilled off, and the safranine is separated in the usual manner.—T. A. L.

Purpurine-sulpho Acid and Purpurine, Manufacture of. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst a. M., Germany. Eng. Pat. 12,094, June 21, 1895.

By oxidising alizarin sulphonic acid in sulphuric acid solution with nitric acid or a nitrate, it is converted into a purpurin sulphonic acid, and this, on heating with concentrated sulphuric acid or dilute mineral acids under pressure, is converted into purpurin. 50 kilos. of alizarin are sulphonated with 200 to 300 kilos. of fuming sulphuric acid (10–20 per cent. SO_3) at 120° – 150° C. until soluble in water. After dilution with sulphuric acid (66° B.), the melt is cooled and has carefully added to it $1\frac{1}{2}$ molecular proportions of nitric acid or a nitrate, the temperature being kept below 10° C. The melt is constantly agitated for about a day, and is finally heated on the water-bath. It is then poured into water, and the purpurin sulphonic acid separated by means of potassium chloride as the potassium salt, which forms sparingly soluble small red crystals. In dilute alkali the product is soluble with a red colour, whilst alizarin sulphonic acid dissolves to a bluish-red. When dyed on an alumina mordant, purpurin sulphonic acid gives a fiery red, much bluer than the shade obtained with alizarin sulphonic acid.—T. A. L.

Azo Colouring Matters [Blacks and Greys], Improvements in the Manufacture of. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 12,529, June 28, 1895.

IN Eng. Pat. 7859 of 1894 (this Journal, 1895, 361) a process is described for the manufacture of dyestuffs by combining equimolecular proportions of a diazo compound and 1,1',4,3'-amidonaphtholdisulphonic acid. It has now been discovered that the amidonaphtholdisulphonic acid will combine with two molecular proportions of a diazo compound, which may be the same or different. The diazo solution from 14.3 kilos. of α -naphthylamine is added to a solution of 34.1 kilos. of the acid sodium salt of 1,1',4,3'-amidonaphtholdisulphonic acid in presence of sodium acetate. When the combination is complete, sodium carbonate is added, and afterwards the diazo derivative from 17.3 kilos. of sulphilic acid, the solution being kept alkaline by means of sodium carbonate. The dyestuff is separated in the usual manner and gives black shades on wool.—T. A. L.

Brown to Black Azo-Colouring Matters Dyeing Direct on Cotton, Manufacture of New. O. Imray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Hoechst a.M., Germany. Eng. Pat. 12,607, June 29, 1895.

THESE are colouring matters of the general formula:—Diazo-compound. N.D.M. diazo-comp., where D is tetrazo-diphenyl or ditolyl, N is 1.1'-dihydroxynaphthalene mono- or disulphonic acid, and M is a *m*-diamine. A number of different examples are given, of which the following may be taken as a typical one:—The tetrazo compound from 2.12 kilos. of tolidine is combined with the azo colouring matter from 2.25 kilos. of diazotised naphthionic acid, and the calculated quantity of chromotrope acid or dihydroxynaphthalene sulphonic acid S, together with 3 kilos. of sodium carbonate. When the formation of the intermediate compound is complete, a solution of 1.08 kilos. of *m*-phenylene diamine is added. The trisazo colouring matter so formed is further combined with the diazobenzene sulphate from 2.31 kilos. of sodium sulphanilate in presence of 1 kilo. of sodium carbonate. The colouring matter is separated in the usual manner. It dyes easily on unmordanted cotton and gives shades fast to light.—T. A. L.

Hydroxyanthraquinone, The Manufacture or Production of Derivatives of. H. E. Newton, London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 12,667, July 1, 1895.

ACCORDING to Eng. Pat. 975 of 1894 (this Journal, 1895, 30), anthraquinone is converted into derivatives of hydroxyanthraquinone when heated in sulphuric acid in presence of boric acid with nitrous acid, or with salts which yield nitrous acid under these circumstances. By treating 8-hydroxyanthraquinone in this manner it might have been expected that purpurin would have been obtained. As a matter of fact the chief product is quinizarin, only small quantities of purpurin being formed. The following are the proportions given in an example:—A solution of 10 kilos. of 8-hydroxyanthraquinone in 200 kilos. of sulphuric acid (100 per cent.) has added to it 10 kilos. of crystallised boric acid and 13 kilos. of sodium nitrite. The melt is kept at 220°–230° C. until it has become an intense yellowish-red, and a considerable amount of quinizarin has been formed, which may be determined by spectroscopic examination. After cooling, the melt is poured into water, heated to boiling, and the precipitate is filtered off. It contains a small quantity of purpurin, which may be removed by treatment with sulphate of alumina solution, in which the purpurin is soluble. The residue, after drying and crystallising from glacial acetic acid, gives pure quinizarin.

—T. A. L.

Direct-dyeing Azo Colouring Matters, Manufacture of. C. D. Abel, London. From "The Actien Gesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 15,947, July 22, 1895.

IN Eng. Pat. 7969 of 1895 (this Journal, 1896, 270), colouring matters are described which are derived from the tetrazo compounds of diamido derivatives having the following general formula:—

in which X and Y are suitably placed amido or hydroxyl groups. It has now been discovered that these diamido compounds may be diazotised by the action of one molecular proportion of nitrite, and the diazo compounds thus formed will combine with one molecular proportion of an amine or a phenol to form strong colouring matters fast to light and acids. For instance, the dark blue diazo solution from 28 kilos. of the diamido compound—

1.1'.2.2'.3.3'.C₁₀H₂.NH₂(OH)(N:N.C₆H₄.NH₂)(SO₃H)₂ and 3.5 kilos. of sodium nitrite in presence of hydrochloric acid, are allowed to run into a solution of 7.2 kilos. of β-naphthol kept alkaline. The colouring matter separates as a dark precipitate, and after agitating for some time it is salted out, filter-pressed, and dried. It dyes cotton a bluish-black.—T. A. L.

New Brown Azo Dye-stuffs and Method of Producing the same. H. H. Lake, London. From K. Oehler, Offenbach a.M., Germany. Eng. Pat. 14,633, Aug. 1, 1895.

THE orange dye-stuff obtained from diazotised tolylene diamine sulphonic acid (CH₃.NH₂.SO₃H:NH₂=1:2:4:6), β-naphthylamine, and *m*-phenylene diamine (Eng. Pat. 17,546 of 1892; this Journal, 1893, 674), can, according to the present invention, be further combined with one molecular proportion of a diazotised amidosulphonic acid—for instance, diazonaphthionic acid—to give a very fast yellowish-brown cotton dye-stuff. The dye-stuff obtained according to the foregoing patent from 10.1 kilos. of tolylene diamine sulphonic acid, 9 kilos. of β-naphthylamine hydrochloride, and 10.3 kilos. of *m*-phenylene diamine sulphate, has added to it the diazonaphthionic acid prepared from 13 kilos. of sodium naphthionate. After stirring for 24 hours the mixture is heated and neutralised with soda, when the dye-stuff formed is salted out, filter-pressed, and dried. It forms a dark brown powder soluble in water with a yellowish-brown and in concentrated sulphuric acid with a dirty violet colour. Hydrochloric acid precipitates the colouring matter in brown flocks from its aqueous solution. It dyes cotton a yellowish-brown.

—T. A. L.

New Colouring Matters Dyeing Cotton without Mordants, Manufacture of. O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 5167, March 7, 1896.

THE process described depends upon the fact that the azo colouring matters obtained from diazobenzaldehyde and a dye-stuff component will condense with hydrazine (diamide) H₂N.NH₂ to form colouring matters which will dye unmordanted cotton. The condensations can be performed in a number of different ways, the specification containing 19 claims. The following may be taken as a typical example illustrating the production of a wool dye-stuff which is subsequently converted into a cotton colouring matter:—8 kilos. of *p*-amidobenzaldehyde hydrochloride and 10 kilos. of hydrochloric acid are dissolved in water cooled with ice and diazotised with 3.5 kilos. of sodium nitrite. After filtering, the solution is run into an aqueous solution containing 16 kilos. of 1.1'.3.3'-amidonaphthol disulphonic acid cooled with ice and containing an excess of sodium acetate. The mixture, after standing 12 hours, is neutralised with soda, which changes the reddish-violet colour to a bluish-violet, and a solution of diazobenzene from 4.7 kilos. of aniline is then run in. The combination is complete in about 12 hours, and after heating to boiling, the colouring matter is salted out and filter-pressed. It forms, when dry, a brown powder, dissolves in water to a blue solution, and gives deep bluish-black shades on wool from an acid bath, fast to fulling. In order to convert it into a cotton colouring matter, 6 kilos. are dissolved in about 200 litres of water, acetic acid is added until the solution is distinctly acid, and then a solution of 0.8 kilo. of hydrazine sulphate in 8 litres of a 10 per cent. sodium carbonate solution is added and the mixture is heated for about three-quarters of an hour, when, after adding an excess of sodium carbonate and letting stand half an hour, the colouring matter is salted out, filter-pressed, and dried. It dyes unmordanted cotton indigo-blue shades.—T. A. L.

Thiazine Colouring Matters, Process for the Transformation of the Thiosulphonates of the Indamines and Indophenols into. O. Imray, London. From "The Society of Chemical Industry in Basle," Basle, Switzerland. Eng. Pat. 5268, March 2, 1896.

IN the preparation of thiazine colouring matters from the thiosulphonates of the corresponding indamines and indophenols the reaction has hitherto been carried out in dilute aqueous solutions at about the boil, in presence of zinc chloride. The patentees propose to effect this transformation, without the presence of water, in sulphuric acid monohydrate, with or without the presence of fuming sulphuric acid, sulphuric chlorhydric, pyrosulphates, chlorides, or the like, at ordinary temperatures or at temperatures between 60° C. and 80° C. The process is appli-

cable to a number of indamine and indophenol thiosulphonates which are mentioned in the claims. A solution of 10 kilos. of tetra-ethylindamine thiosulphonate in 50 kilos. of fuming sulphuric acid (24 per cent. SO_3) is heated at 80—100° C. until of a deep green colour. After cooling somewhat, the melt is poured into 300 litres of water and mixed with salt and 50 kilos. of a 20 per cent. zinc chloride solution. The ethylene blue gradually crystallises out in green bronzy needles.—T. A. L.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

PATENTS.

Klof, Ramie, and China Grass, Improvements in the Treatment of. R. W. E. Melvor and J. Chester, London. Eng. Pat. 12,218, June 24, 1895.

The material, in strips or ribbons, is boiled for $\frac{1}{2}$ —2 hours in a 2 per cent. solution of borax. At the end of this period there is added to the solution a composition consisting of four parts of soft soap and one part of oil containing 5—10 per cent. of its bulk of turpentine, the whole mixture forming about one-tenth of the liquid in the vat. Boiling is continued until the bark and fibre are readily separated, and the material is then washed in hot water and dried.—R. B. B.

Silk and Silk Waste, Improved Process for Loading. C. E. Fuller and A. Biermann, Crefeld, Germany. Eng. Pat. 5332, March 11, 1896.

In addition to the successive treatment with stannic chloride, sodium phosphate, and sodium silicate comprised in the usual process, the silk is further treated in a solution of an aluminium salt at 1—15° B., in which the material is heated for 20—90 minutes. It is claimed that by this means an increased weight of 50 per cent. for each application is obtained, and that durability is also enhanced.—R. B. B.

VI.—DYEING, CALICO PRINTING, PAPER-STAINING, AND BLEACHING.

Lactic Acid, its Properties and Uses in Dyeing, Printing, and Finishing. C. Dreher. *Färber Zeit.* 1896, 7, 233—236. (See also this Journal, 1882, 363; 1883, 176; 1885, 116; 1886, 677; 1891, 362; 1896, 196; also J. Soc. Dyers and Col., 1895, 98.)

The author has now used lactic acid in wool-dyeing for two years, and has studied its properties for other possible uses.

Lactic acid has the advantage over oxalic acid that it is not poisonous, and over acetic acid that it is not volatile. Its viscosity in the pure state is greater than that of glycerin; it wets and penetrates both animal and vegetable fibres easily, and imparts to the fabric a soft feel, as glycerin does. Of greatest importance, however, is its property of being readily oxidisable by chromic acid.

Lactic acid being readily oxidised at low temperatures, it is best to let the oxidation proceed at 52·5° C., and to raise to boiling only towards the end. The wool should be well washed and wetted out before entering, and the oxidation is to be promoted by the addition of a little sulphuric acid rather than by continued boiling, which is detrimental to the fibre.

Author recommends as the most suitable proportions: 2·5 kilos. of lactic acid (30 per cent.), 2·75 kilos. of potassium bichromate, and 0·5 kilo. of sulphuric acid, which gives the same results as with 2·5 kilos. of best refined tartaric acid, 3·0 kilos. of potassium bichromate, and 0·35 kilo. of sulphuric acid.

Dyeing operations on wool mordanted as above showed very "fiery" results; the material had a fine, soft "handle" and a beautiful lustre, and was superior in respect of these qualities to dyeings where tartaric acid had been used.

Trials with pure lactic acid have shown that it is particularly suitable for printing on wool, but with acid dyestuffs (sulphonic acids) it has been found too weak. In combination with sulphuric or tartaric acid, however, much better

results as regards evenness and depth of shade are obtained, particularly with "Brilliant" and "Naphthol blacks," than when sulphuric or tartaric acid is used alone. The printing composition wets exceedingly well. A saving in tartaric acid may be effected by substituting lactic acid for a part of it; but too much of the lactic acid must not be used, as otherwise the colour is liable to "run" during steaming.

In many cases lactic acid may also take the place of glycerin both for printing and finishing, and particularly where its feebly acid character is without detriment it may be useful for vivifying the colour.—I. S.

Electrolytic Bleaching. M. G. Saget. *Monit. Scient.* 1896, 257—258.

The author has investigated, comparatively, the action upon cellulose of Hermite's solution, obtained by electrolysis of a solution of magnesium chloride and sea salt; Gebauer-Knoeffler's solution, which is prepared by electrolysis of sodium chloride solution free from magnesium chloride, and a solution of ordinary bleaching powder.

According to the descriptive pamphlet by Dübosc, oxycellulose is not formed by Hermite's liquor; but Gebauer and Knoeffler raised the question by stating, in their circular, that as salts of lime and magnesia are absent from their solutions, the formation of spots due to these salts is avoided. The author's experiments show that just the same precautions are necessary with the electrolytic solutions as with ordinary chloride of lime solution. Two series of experiments were made. In the first series, the tissue was completely immersed in the liquid and exposed to the sun; under these conditions, oxycellulose was not formed with Gebauer's solution provided the available chlorine was less than 0·25 gm. per litre; or with Hermite's liquor if the chlorine did not exceed 0·26 gm.; but with ordinary bleaching powder solution, as much as 0·54 gm. chlorine might be present. In the sun, therefore, the action of the electrolytic solutions is more energetic than that of bleaching powder solution. In the second series of experiments, the tissue was partially immersed, in the shade, the liquid being drawn up into the fabric by capillarity. In this case, chloride of lime was the most active, oxycellulose being distinctly formed even with less than 0·30 gm. chlorine per litre, whilst the Hermite and Gebauer liquors of the same available strength formed none.

As it appeared possible that free chlorine might be present in the electrolytic liquor, an experiment was made with chlorine water; but not a trace of oxycellulose was formed in the shade, even with a concentration of 2 gm. per litre. On the contrary, with exposure to the sun, free chlorine energetically attacks the tissue, unless the strength of the solution fall below 0·25 gm. per litre.

A solution of magnesium hypochlorite, prepared by the action of a current of chlorine upon magnesia suspended in water, behaved very much like Hermite's solution; but a solution prepared by double decomposition between magnesium sulphate and chloride of lime, behaved exactly like bleaching powder solution.

Comparative results show that Hermite's solution is more active than Gebauer's, due no doubt to the instability of magnesium hypochlorite. Not improbably, by electrolysis, a more active persalt of magnesium is formed, which adds its effects.

It is not surprising that, in the experiments made in the shade, bleaching powder solutions gave most oxycellulose; this is attributable to the presence of free alkali, which is known to facilitate the oxidation of cellulose.

As a bleaching agent, Hermite's solution is the most active, Gebauer's next, and chloride of lime least. Very good pure whites may be obtained with Hermite's solution, containing not more than 0·30 gm. active chlorine per litre; to obtain the same result with bleaching powder, a solution of almost double the strength is required. Hermite's solution of the strength named is harmless to the cotton fibre, and the formation of oxycellulose is prevented by exclusion of the direct rays of the sun.—L. A.

Cellulose, Action of Nitric Acid on. E. Kuecht. J. Soc. Dyers and Colourists, 1896, 12, 89—90.

If cotton be placed for 15 minutes in pure nitric acid of 82° Tw. and then washed and dried, it is found that considerable contraction of the fibre results and that the material increases in weight and tensile strength. More dilute acid tenders and weakens it. Analysis shows that partial nitration of the cellulose has occurred, and its behaviour towards direct cotton dyestuffs, from which baths it takes a three or four times deeper shade than ordinary cotton, points to the fact of mercerisation. It will not dye with basic colours, hence, argues the author, no oxycellulose has been formed. The use of strong nitric acid for stripping certain colours and for mercerising, is suggested.—H. I.

Cotton, A New Method of "Animalising." E. Kuecht. J. Soc. Dyers and Colourists, 1896, 12, 90—91.

250 grms. of wool are dissolved in an equal weight of barium hydrate. The barium is then precipitated with carbon dioxide, the clear solution made up to 1 litre, and 10 per cent. of commercial formaldehyde (40 per cent. strength) added. Cotton, when padded with this solution, dried, and steamed for half an hour under pressure (15 lb.), after washing, may be dyed directly with any acid or basic dyestuff, but the shades produced are not so fast as on wool.

The author has not been able to animalise cotton by L. Vignon's process, *viz.* treatment with zinc or calcium chloride and ammonia under pressure.—H. I.

Manganese Bistres, Albumin Discharges on. A. Brandl. Bull. Soc. Ind. de Mulhouse, 1896, 79.

AFTER trials with various reducing agents, the best results were obtained with a printing colour in which sodium bisulphite and ammonium sulphocyanide formed the reducing agents. The printing colour was prepared by mixing 350 grms. of British gum with 200 grms. of glycerin and 1,350 grms. of sodium bisulphite (40 B.). This mixture was heated to 50° C. on the water-bath, and, after cooling, 500 grms. of albumin solution (50 per cent.) and 1,000 grms. of ammonium sulphocyanide were added, dissolved by agitation, and strained. For printing, 1,000 parts of thickening to from 750 to 1,000 of the above printing colour are used. After printing, the goods are steamed for from 2 to 3 minutes, lightly washed, and dried.—C. O. W.

Paper Colouring [in the Engine]. H. Spitteler. Papier Zeit. 21, 1896, 763.

The author advises, in certain cases, the addition of albumin as an auxiliary in dyeing pulps in the engine with soluble dyestuffs. The quantity required is 0.5 to 1.0 per cent.

It should be added to the stuff when half beaten. It is rendered insoluble, and therefore becomes fixed, by the alum subsequently added.—C. F. C.

Mercerising, Improvements in Effects obtained by. W. E. Kay. Textile Colorist, 1896, 18, 101.

In this method, in the case of aniline black, the fabric is first treated with a solution capable of forming aniline black when steamed. That portion of the pattern which is to be felled ("crinkled") is next treated with a thickening prepared from a highly baked dextrin, which acts as a resist to the mercerising material, and to this is added an aniline black resist, and, when desired, a suitable colour. The black is then developed on the ground, the printed portions resisting it. After this, the fabric is padded with a solution of caustic alkali (about 54° B.), which shrinks the portions not treated with gum resist, and so produces the crinkling of the pattern. After leaving the padding machine, the fabric is allowed to lie for a short time, to let the caustic complete its action, prior to washing and finishing.

In the case of ordinary dyes, the process is analogous. The fabric is first dyed all over, the pattern which is to be crinkled is printed with a gum resist to prevent mercerisation, but, in addition, chemical reagents capable of discharging or destroying the dye when subjected to steaming, are admixed, and also, when desired, a suitable colour. After steaming to effect the discharge, the non-printed part is mercerised by padding with caustic soda as before.

The resist and discharge materials may sometimes be printed before the fabric is dyed.—A. S.

Soluble Colloids, such as Gelatin and Isinglass, Improvements in the Formation and Preparation of. E. J. Mills. Glasgow. Eng. Pat. 8847, May 4, 1895.

See under XIV., page 462.

Beta-Naphthol on the Fibre, Process for the Partial or Total Destruction of [in Calico Printing], by Oxidation by Means of Persulphates. O. Inray, London. From "The Farbwerke vormals Meister, Lucius, and Brüning," Höchst a Main, Germany. Eng. Pat. 12,162, June 22, 1895.

To obtain coloured discharge effects with the naphthol-azo colouring matters produced directly upon the cotton fibre, the only possible process appears to be that in which the discharge colours are also naphthol-azo compounds. For this purpose a substance must be added to the printing colour, which, after the formation of the dye, prevents the naphthol from further coupling when worked in a diazo solution; such substances the inventors have discovered in the persulphates. As an example of the process, the goods after preparation with β -naphthol are printed with a blue discharge colour consisting of diazotised d'anisidine, copper chloride, ammonium persulphate, stannic chloride, and suitable thickening. The addition of stannic chloride is found to increase the effect of the persulphate. The goods are then dyed in a solution of diazotised paranitraniline, to which acetate of soda and ammonium oxalate are added.

Fibre, Vegetable and Animal: Improvements in Apparatus for Treating with Liquids. J. F. Lester, Atlanta, Georgia, U.S.A. Eng. Pat. 6318, March 21, 1896.

THE dyeing, bleaching, or scouring liquid is caused to circulate through a cylindrical digesting vessel. Along each side of this vessel a series of pipes is arranged, one series connected with the inlet, the other with the outlet for the liquid. Joining these is a number of transverse pipes, alternately communicating with the first and second series above described. Those connected with the inlet series are perforated tangentially, and are capable of revolving, thus distributing the liquid in a spray through the fibre, which is placed in wire cages between the pipes. The transverse pipes communicating with the outlet series are rigid and perforated radially, and serve to remove the liquid from the digester.—R. B. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Cyanogen, Formation of, from Ammonia. E. Bergmann. J. für Gasbeleucht. 1896, 39, 117.

THE experiments of Bueb are first recapitulated. Bueb found that only a small quantity of hydrocyanic acid was produced by the action of ammonia upon charcoal at 800° C., about 4 per cent. of the nitrogen of the ammonia being converted into cyanogen. At 1,000° C. he found that 24 per cent. of the nitrogen became combined as cyanogen. On passing a mixture of ammonia and coal-gas over charcoal heated to between 1,150°—1,180°, 60 per cent. of the nitrogen was recovered as cyanogen, 20 per cent. remained as undecomposed ammonia, and 20 per cent. was liberated as free nitrogen. The author has continued Bueb's investigations, and has examined into:—(1.) The influence of coal-gas upon ammonia in the

presence of red-hot charcoal. (2.) The influence of carbonic oxide, producer gas, &c. (3.) The influence of temperature upon the yield of cyanogen.

(4.) Five experiments were made by passing coal-gas and ammonia over heated charcoal. Hydrocyanic acid, and not ammonium cyanide, was produced. A table gives the data of the experiments.

(5.) When the coal-gas was carburated with pentane, the cyanogen formation increased as the amount of pentane decreased. The author explains this by ascribing it to the dilution of the ammonia by the products of decomposition of the pentane.

(6.) When carbonic oxide, producer gas, and mixtures of hydrogen and nitrogen were used instead of coal-gas, the formation of cyanogen proceeded in the same way as with coal-gas, except that more of the ammonia was decomposed.

Experiments with ammonia and carbonic oxide without charcoal gave only minute quantities of cyanogen. The most favourable temperature for the formation of cyanogen was found to lie between 1,000 and 1,100°.—H. S. P.

PATENTS.

Acid Vapours, Improvements in Condensing and Cooling Apparatus for. E. Hart, Easton, Pennsylvania, U.S.A. Eng. Pat. 12,383, June 26, 1895.

This is an improvement on Eng. Pat. 17,289, 1894 (this Journal, 1197, 1894), wherein an apparatus is described and shown for condensing nitric acid and other vapours, the condensing chamber of which consists of a number of parallel glass tubes, cooled by a fall of water delivered from a pipe over the topmost tube. To prevent fracture of these tubes, while heated, by the cold water, it is now provided that they be covered by some porous material serving to distribute the water (which may be warmed) over the whole surface. Preferably, each tube is separately wrapped in cheese cloth. A heater is shown through which the water for sprinkling may be passed. In other respects the apparatus conforms to that shown in the abstract cited.

—E. S.

Zinc Chloride and other Metal Chlorides, Improvements in and relating to the Manufacture of Solutions of. C. Hoepfner, Giessen, Germany. Eng. Pat. 8449, April 29, 1895.

Zinc oxide, obtained, for instance, by roasting zinc blende, is treated with sulphurous acid, any excess of acid is distilled off or neutralised, and the zinc sulphite is decomposed by a solution of calcium chloride, to obtain zinc chloride in solution. The precipitated calcium sulphite may be dissolved by sulphurous acid, and utilised for the manufacture of wood pulp. Zinc sulphite obtained as described may be oxidised by exposure to warm air, or to oxygen or chlorine, and the resulting sulphate be decomposed by sodium or potassium chloride: the alkali metal sulphate is then crystallised out, zinc chloride being left in solution. Zinc and chlorine may be obtained from the solution by electrolysis.—E. S.

Salt, Improvements in or relating to the Manufacture of. E. P. Gutierrez, Cabezon de la Sal, Spain. Eng. Pat. 1729, Jan. 24, 1896.

There is claimed "the combination with a process of melting salt and moulding it afterwards, for the use of animals, of the utilisation of the heat from the melting furnaces for manufacturing salt for cooking purposes, by evaporating salt water in suitable boilers," &c.—E. S.

Silicic Acid from Argillaceous Substances [Sulphate of Alumina and Compact Silica], An Improved Process for the Separation of. F. Brünjes, Langelsheim am Harz, Germany. Eng. Pat. 6157, March 19, 1896.

The attack of argillaceous substances by waste sulphuric acid from tar and oil refining is attended by the difficulty that, owing to the organic matter present, the sulphate of alumina formed is impure and strongly coloured. The patentee seeks to remove this disability and at the same time to obtain the silica separated from the clayey material in a filterable condition, by adding molasses, starch, &c. in the proportion of 0.1 to 0.5 per cent. for each 1 per cent. of silica to be set free.—B. B.

VIII.—GLASS, POTTERY, ENAMELS.

Metallic Deposits on Porcelain, Glass, &c., Production of. Hansen. D. Töpfer- und Ziegler Zeit. **19**, 774.

To prepare the surface of glass or porcelain for the production of these metallic deposits by the electrolytic method, the author makes use of a solution of gold or platinum salt in ether, to which is added sufficient of a solution of sulphur in paraffin oil to render the mixture of a consistency such that it can be readily applied with a brush. The article so treated is then heated in the kiln.

For the production of copper, silver, or gold deposits, the following baths are recommended:—*Copper*:—2 parts of copper sulphate in 3 parts of distilled water. *Silver*:—17 parts of silver nitrate and 13 parts of potassium cyanide in 300 parts of distilled water. *Gold*:—7 parts of metallic gold are dissolved in aqua regia and precipitated with ammonia; the moist precipitate is then dissolved in a hot solution of 9 parts of potassium cyanide in 90 parts of distilled water.—J. G. W.

PATENTS.

Muffle Furnaces [Pottery and Enamels], Improvements in. A. Helzel, Bodenbach, Austria-Hungary. Eng. Pat. 10,067, May 21, 1895.

The muffle consists of an annular channel, one section of which serves as a burning chamber, one as a cooling chamber, and one as a preliminary heating chamber. The goods to be fired are carried on trollies running beneath the annular space and provided with supports projecting upwards into the annular space. The lower part of the annular space is sealed by a sand joint. The process of burning can be carried out continuously by the rotatory movement of the chain of trollies along the annular muffle. An alternative method of construction is also described.

—B. B.

Earthenware, Improvements in the Manufacture of. E. Bilton, Fenton, Stoke-on Trent. Eng. Pat. 10,079, May 22, 1895.

To the raw material of earthenware containing red marl or clay, barium carbonate (or other barium salt) is added in the proportion of about 1:10 for the purpose of lightening the colour of the finished goods.—B. B.

Composition, Improved, for Use in the Plastic Arts. J. L. Rawdon and The British and Foreign Patent Syndicate, Limited, Manchester. Eng. Pat. 11,595, June 14, 1895.

One pound of commercial silicate of soda solution is mixed with 1 oz. of dry powdered calcium chloride and $\frac{3}{4}$ oz. of slaked lime; 12 oz. of the mixture are used to render plastic 1 lb. of pipeclay or potter's clay, previously ground and sifted. Borax and colouring materials may be added, and silicate of potash may be substituted for silicate of soda. The product is used as modelling clay which will dry without cracking, and can be fired if necessary, and as a substitute for moulding sand.—B. B.

Pottery Ware and like Glaze-firing Furnaces and Kilns, Improvements in and relating to. C. Mayer, Oeslau, Germany. Eng. Pat. 5622, March 12, 1896.

CONTINUOUS and systematic firing of ceramic goods in muffles is secured by the use of a series of kilns, to any one of which

a shifting furnace may be applied. Air to feed the furnace is drawn from previously heated kilns, and similarly the products of combustion from the kiln in process of firing are turned through the kilns about to be fired.—B. B.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Cement. E. Candlot. Bull. Soc. d'Encouragement, 1895, 1278—1313.

THE article consists chiefly of a review of the improvements which have been introduced from time to time in the process and plant used in the manufacture of cement. The

following statements may be reproduced:—In French practice it is customary when making cement by the wet method to allow the slurry flowing from the wash mill to pass into tanks of 100—150 cb. m. capacity, provided with agitators running at 20—30 revolutions per minute. A further blending of the raw materials is thus effected, and greater homogeneity is obtained than when the slurry passes direct from the wash mill to the "backs." The usual samples for analysis needed to check the composition of the slurry are taken from these mixing tanks.

In the United States a rotating cylindrical furnace fed by petroleum is said to be successfully used. As shown in the figure, it has a burning cylinder into which a jet of burning petroleum is introduced, and a cooling cylinder

down which the clinker passes, regeneratively heating the incoming air. The dried slurry is fed in as a powder and is completely burnt in traversing the upper cylinder, its passage through which takes about half an hour. It is alleged that attempts to substitute producer gas for petroleum have not been successful.—B. B.

Dinas Bricks. E. Seger and E. Cramer. Stahl und Eisen, 1895, 1084—1087.

BRITISH Dinas firebricks are sometimes preferred in Germany to the home-made product, without adequate reason. In comparing the quality of bricks of different origins, the following tests were used:—(1.) The toughness of the brick was adjudged by noting its ring when struck by a hammer. (2.) The fusing point of the brick was taken in a Deville furnace, using Seger's cones as a means of comparison. (3.) Its degree of permanence as regards volume before and after firing, was determined. The following table of analyses shows the small differences existing between British and German Dinas bricks:—

	SiO ₂	Al ₂ O ₃ + Fe ₂ O ₃	CaO
British, No. 1.....	97.40	1.19	1.11
" No. 2.....	96.80	2.23	0.97
Homburg.....	95.40	1.19	3.20
Eschweiler, No. 1.....	96.24	2.36	1.40
" No. 2.....	96.54	2.03	1.43

All five samples fused between 2,120 and 2,150° C.; no difference could be detected in this respect. As regards constancy of volume, however, the German are said to be better than the British bricks.—B. B.

Bricks Refractory to the Action of Fused Alkalis and Alkaline Sulphides. W. Hempel and W. Jezierski. Chem. Ind., 1896, 179—181.

CERTAIN stones are found in Norway, South Tyrol, and North America, called "pot-stones," which are soft in their

native state, but attain a considerable hardness when burnt. The material of which these stones are composed is a mixture of talc, chlorite and dolomite; it resists the action of fused alkalis and alkaline sulphides almost completely. A sample analysed, had the following ultimate composition:—SiO₂, 44.3; CaO, 3.4; Fe₂O₃, 4.2; FeO, 7.6; Al₂O₃, 4.3; MgO, 20.7; Na₂O, 4.7; Cl, 0.2; and H₂O, 10.6 parts per cent. respectively. Test pieces exposed to the action of fused caustic soda, alone, and mixed with 40 per cent. of sulphur, lost only a trifling weight, whereas a piece of ordinary firebrick under like conditions lost more than half its weight. The fusing point of the stone is above that of cast iron, but below that of steel. Attempts were made to prepare artificial stone of approximately the same composition from the following raw materials:—

(1) Loam or brick earth containing—SiO₂, 72.82; Fe₂O₃, 4.04; Al₂O₃, 10.48; CaO, 0.62; MgO, 0.31; Na₂O, 5.66; CO₂, 0.09; H₂O, 5.63 per cent.; and (2) Crude magnesia from the magnesium chloride process for making HCl and Cl₂ as carried out at Stassfurt, having the composition—SiO₂, 3.42; Fe₂O₃, 0.12; Al₂O₃, 5.15; MgO, 83.76; Cl, 0.65; SO₂, 1.89; CO₂, 0.75; H₂O, 3.97 per cent.; or as an alternative—(3) Dolomite containing SiO₂, 5.13; Fe₂O₃, 2.33; FeO, 1.56; CaO, 27.86; MnO, 2.75; MgO, 16.84; CO₂, 42.35; H₂O, 0.8 per cent.

From these raw materials it is impossible to obtain a mixture containing both SiO₂ and MgO (the dominant acid and base) in the same percentage as those present in the natural stone. Taking SiO₂ as a basis for calculation, it is found that 100 parts of crude magnesia and 142 parts of loam will yield a substance of the right composition as far as SiO₂ is concerned. Taking MgO, however, as the criterion, there were required 100 parts of magnesia to 309 parts of loam. The first mixture when strongly heated in a graphite crucible gave a product which resisted the action of caustic alkali and alkaline sulphide very well; the second mixture withstood an alkaline sulphide fusion, but was attacked by caustic soda. Both mixtures did not fuse at the temperature of molten cast

iron, but ran down at a temperature high enough to melt steel.

Using dolomite as a source of magnesia, a mixture from that and the same loam was prepared, taking the percentage of silica as a basis for calculation. The actual proportions taken were 236 parts of dolomite and 325 parts of loam, and the product resisted the action of caustic soda, alkaline sulphide, and strong hydrochloric acid, and was less fusible than the natural stone. The use of such artificial stones therefore appears to be practicable.—B. B.

PATENTS.

Cement, Improved, for firmly binding together Light Substances. A. Hafter, Glasgow. Eng. Pat. 9861, May 18, 1895.

CLAY is treated with such quantity of sulphuric acid as will yield 50 per cent. of soluble sulphates in the product. Poor clay is improved by the addition of a soluble sulphate. To 100 parts of this material 10 parts of "an amylaceous substance" are added, the resulting mass being suitable for cementing together light substances, e.g. textile fibres, peat, and cork shavings.—B. B.

Cement Concretes, Improvements in the Manufacture of. S. G. Bird and J. Wright, London. Eng. Pat. 10,207, May 23, 1895.

WHAT is known in the trade as "slag" is mixed with about 5 per cent. of ferrous sulphate and the product is mixed with cement. Cement concretes are thus said to be rendered "harder and more durable."—B. B.

Cement Manufacture, Improvements in the. W. Stark, London. Eng. Pat. 11,267, June 8, 1895.

SUGGARY is made in the way usual for the manufacture of Portland cement, but with a somewhat higher proportion of chalk. This is loaded into the kiln together with Roman cement stone in such proportions that the ratio of acid to basic oxides in the whole mass is normal for Portland cement. The mixed material is burned and ground in the usual way.—B. B.

Plaster, Improvements in the Manufacture of. J. C. Bloomfield, Leggs, Ireland. Eng. Pat. 12,382, June 26, 1895.

100 PARTS by volume of hydraulic lime are mixed with 5 parts by volume of sulphate of lime (preferably plaster of Paris) and 5 parts by volume of finely-ground shale. The product may be coloured with oxide of iron or ochre, and used as a plaster.—B. B.

Cement, A New or Improved. A. Clery, London. Eng. Pat. 3985, February 21, 1896.

THE material patented consists of (1) powdered marble, 75 parts; zinc oxide, 12 parts; powdered sandstone, 10 parts; and (2) Muriatic acid, 90 parts; zinc, 10 parts; prepared separately, and mixed as wanted in the proportion of 2:1; the proposed use of the cement is as a substitute for Portland, Roman or Keene's cement.—B. B.

Cement Manufacturing, Improvements in the Art of. R. A. Cheseborough, New York, U.S.A. Eng. Pat. 4918, March 1, 1896.

THE process patented consists in showering slurry in powder down a vertical kiln provided with crossbars and heated by an ascending flame emanating from a petroleum jet at the base of the kiln. The slurry is fed in by a conveyor, hopper and screw, and the clinker withdrawn from a hopper-shaped opening at the bottom of the tower. The products of combustion on their way to the chimney are led down a vertical flue forming part of the kiln, and serve to raise steam for power and for driving the oil-jet.—B. B.

Artificial Stone, The Manufacture of an, and the Manufacture of Various Articles therefrom. W. H. Metcalfe, Plaistow, and F. B. Wrightson, London. Eng. Pat. 9283, May 10, 1895.

BROKEN pottery and earthenware ("schraff") saggers and the like are crushed, sized by sifting, and mixed with

Portland or other cement in the proportion of 60—75 per cent. of the former to 40—25 per cent. of the latter. The mixture is moistened and moulded into slabs, sills, mantelpieces and similar articles.—B. B.

Artificial Stone, Improvements in the Manufacture of. E. M. Arndt, Stettin, and G. de Bruyn, Hamburg, Germany. Eng. Pat. 12,242, June 24, 1895.

A CEMENTITIOUS mixture of gypsum and caustic lime is treated with sulphurous acid or a sulphite, in order to convert the lime into calcium sulphite, which may ultimately, by oxidation, crystallise as sulphate. Silicic acid may be added to unite with a further portion of the lime, and simultaneously aluminium sulphite may be used, so that there may be formed "a double silicate with the silicic acid and with the base set free by the lime from the sulphite employed." Cinders, sand, infusorial earth, and the like may be added. The product is used for the manufacture of artificial stone.—B. B.

Artificial Stone Blocks or Plates, An Improved Method of and Apparatus for Making. P. Jantzen, Elbing, Germany. Eng. Pat. 23,980, Dec. 14, 1895.

THE apparatus patented consists of a mould for the reception of the plastic material from which the blocks are to be prepared, resting on a rising pillar, bearing in its turn on a pawl gearing with a ratchet wheel driven by a horizontal shaft. The rotation of the shaft and the consequent rising and falling of the pawl over the teeth of the ratchet wheel, communicate a series of vertical shocks to the pillar and mould borne thereby, the motion thus obtained consolidating the mixture in the mould. A lever serves to raise the pillar and eject the plate or block from the mould when the shaking is complete. Surplus water appearing on the surface of the block is removed by placing a slightly moistened layer of mortar thereon, and applying heavy pressure.—B. B.

Artificial Stone, Improvements in the Manufacture of. W. P. Thompson, London. From La Société Anonyme la Néo-Litho, Moll, Belgium. Eng. Pat. 3800, Feb. 19, 1896.

AN artificial sandstone of close texture is said to be made from: silica, 40 per cent.; hydraulic lime, 20 per cent.; oxide of alumina, 20 per cent.; oxide of potassium or sodium, 10 per cent.; oxide of calcium, 5 per cent.; oxide of iron, 5 per cent., mixed, moulded, and subjected to the action of high-pressure steam.—B. B.

Mortar Analysis, [Time] Precipitation Process of. J. Patchett, Birmingham. Eng. Pat. 10,089, May 22, 1895.

See under XXIII., page 474.

Mortar Analysis, Measure Process of. J. Patchett, Birmingham. Eng. Pat. 10,090, May 22, 1895.

See under XXIII., page 474.

Asphalt Composition or Covering, An Improved Protective. R. D. Upham, New York, U.S.A. Eng. Pat. 24,479, Dec. 20, 1895.

THE composition patented consists of about 70 parts of copper filings and 30 parts of "asphaltic cement," the latter being composed of 43 parts of pure refined asphalt, 7 parts of "flux," and 50 parts of pulverised silica. The resulting mixture is applied hot as a coating for ships, as a roofing composition, or in any connection in which a waterproof coating is required.—B. B.

X.—METALLURGY.

Magnetic Iron Sands, New Zealand, Treatment of. E. M. Smith. Iron and Steel Institute, Spring Meeting, 1896. The Ironmonger, 265, 266.

AT New Plymouth, Taranaki, New Zealand, magnetic iron sand occurs as a beach deposit 14 ft. deep, extending about 13 miles along the shore, and at least three miles out to sea. It is a product of the degradation of neighbouring cliffs, and when any of it is removed from the beach the

incoming tide replaces it. Furthermore, there is coal, limestone, and timber in the vicinity. The composition of the iron sand is 82 per cent. of iron oxides, 8 per cent. of titanium oxide, 8 per cent. of silica, and 2 per cent. of water and loss, and, when made into bricks by pugging with about 15 per cent. each of yellow and blue clay, consisting chiefly of silica and alumina with about 9 per cent. of oxide of iron and small quantities of lime and magnesia or alkalis, and smelting these bricks in a blast furnace with half their weight of a flux consisting chiefly of lime, it has yielded metal of the following composition:—

	Pig Iron.	Bar Iron.
	Per Cent.	Per Cent.
Iron.....	94.09	98.94
Manganese.....	Traces	Traces
Titanium.....	1.00	0.21
Silicon.....	2.12	..
Sulphur.....	0.02	Traces
Carbon.....	2.33	0.46
Loss and undetermined.....	0.44	0.39
	100.00	100.00

The pig iron is fairly granular, the bar iron fine-grained and of excellent quality.—A. W.

Iron, The Influence of Carbon on. J. O. Arnold. Proc. Civil Eng. 123, [1], 6—41.

THE author, in a paper of some length, deals with the influence of carbon on iron. The chief points are given in a general summary of the paper.

The constituents of steel may be:—(a.) Crystals of pure iron, which remain bright on etching. (b.) Crystals of slightly impure iron, which become pale brown on etching, probably due to a small quantity of an intermediate carbide of iron, Fe_{10}C (?). (c.) Normal carbide of iron, Fe_3C , which exists in three distinct modifications, each one giving particular mechanical properties to the iron in which it is found. (1.) Emulsified carbide present in an exceedingly fine state of division in tempered steels. (2.) Diffused carbide occurring in normal steels in small ill-defined stric and granules. (3.) Crystallised carbide occurring as well-defined laminae in annealed and in some normal steels. (d.) Sub-carbide of iron, Fe_{23}C , a compound of great hardness, existing in hardened and tempered steels. This compound is decomposed by the most dilute acids, and at 400°C . it splits up into Fe_3C and free iron, with evolution of heat. It has a remarkable capacity for permanent magnetism. (e.) Graphite or "temper carbon."

The existence of Fe_{23}C is proved by the fact that iron containing 0.89 per cent. of carbon presents several correlative critical points when examined by different methods of observation.

The influence of annealing is:—(1.) To increase the size of crystals and also the inter-crystalline cohesion.

TABLE GIVING APPROXIMATE THEORETICAL CONSTITUENTS OF HARDENED AND NORMAL IRON AND CARBON STEELS REQUIRED BY THE SUB-CARBIDE THEORY.

Carbon.	Hardened Steels.				Normal Steels.	
	Fe.	Fe_3C .	Fe_3C .		Fe.	Fe_3C .
Per Cent.	Per Cent.	Per Cent.	Per Cent.		Per Cent.	Per Cent.
0.1	89	11	0		99	1
0.2	78	22	0		97	3
0.3	67	33	0		95	5
0.4	56	44	0		93	7
0.5	45	55	0		91	9
0.6	34	66	0		89	11
0.7	22	78	0		87	13
0.8	11	89	0		85	15
0.9	0	100	0		84	16
1.0	0	99	1		82	18
1.1	0	97	3		81	19
1.2	0	95	5		79	21
1.3	0	93	7		77	23
1.4	0	91	9	
1.5	0	89	11	

(2.) To convert elongated masses of iron containing diffused Fe_3C into compact rounder bodies containing laminae of crystallised Fe_3C , between which the iron becomes more or less dove-tailed throughout the mass.

The sub-carbide theory accounts for several facts that are observed in every-day experience. For instance, steel containing 1.3 per cent. of carbon would be useless for steel which has to carry a cutting edge and yet be able to withstand a shock. The reason is that such a steel is full of lines of weakness along the junction of the sub-carbide granules with the normal carbide membranes. For turning tools, a steel containing more than 0.9 per cent. of carbon is necessary, as in this case no shock has to be encountered, and the normal carbide simply augments the hardness of the sub-carbide. It is also evident that a steel with much below 0.9 per cent. of carbon cannot carry a cutting edge on account of the presence of soft free iron amongst the hard sub-carbide.

The author points out that on heating a saturated steel in air, the surface of the metal falls below saturation point, owing to the oxidation of some of the carbon; whereas in a steel containing, say, 1.2 per cent. of carbon, the membranes of Fe_3C act as reserves to replace the oxidised carbon, and thus the steel is maintained in a saturated condition.

The paper is accompanied by 10 drawings and a set of 19 photographs.—A. S.

Iron Carbides, Some Alloys with, mainly Manganese and Tungsten. J. S. De Benneville. Iron and Steel Institute, Spring Meeting, 1896. The Ironmonger, 298—311.

ANALYTICAL data indicate that liquid iron does not differ as a solvent from other liquids, except in the comparatively great complexity of its molecular structure. On the cooling of such a mass containing in combination with it other elements, according to the conditions of such cooling, and the volume and the chemical affinity of such elements for the solvent, the solidified mass would present a structure homogeneous throughout, through intermediate forms, to a highly segregated and crystalline condition in which a number of definite compounds have been formed. Such definite compounds in iron are present in two forms: (1) Compounds common to alloys of wide range of composition, Fe_3C , and the prismatic forms found in manganese and chromium carbides, phosphides, and sulphides; (2) Compounds varying in composition from one alloy to another, and dependent within narrow limits on the conditions of cooling, and often on the immediately surrounding magma from which the constituents are drawn. Such are the granular residues, differing only in degree from the ground-mass of the alloy. With the ground-mass of the alloy, directly comparable with vitreous structure of basalts, there is found a regular gradation in iron alloys, and they are to be classed according to the amount of differentiation undergone. Iron carbides tend to form homogeneous masses in which definite compounds are of minor importance, the great bulk of the alloy entering into the ground-mass. Rapid cooling preserves this structure, whilst slow cooling promotes crystallisation. Owing to their tendency to form ground-mass, iron carbides are more subject to control even in the presence of elements with which they form inert compounds; if present in small quantity, limits of homogeneity are comparatively wide. To a considerable extent this is also the case with ferro-manganese, but definite compounds assume a more regular form, and the granular masses form a considerable percentage of the total mass. In carbides with the sixth family—tungsten, molybdenum, and chromium—definite crystallised compounds are an important factor, and the dominant influence of the added element is shown in the chemical inertia of the granular residue, sharply differentiating them from the soluble portion to an extent not found in iron carbide or ferro-manganese, in which the separation chemically from the ground-mass is not marked. Such elements, when present in large quantities, are less capable of control. Although manganese and tungsten form a ternary carbide with iron, the chemical properties of the manganese, when present in sufficient quantity, class the

resultant product in its reactions with ferro-manganese. When tungsten is present in large proportion as compared with manganese, the latter is masked; this refers to large proportions. In small quantities their action should be almost independent of each other.

Proximate analysis of the alloys shows that outside of phosphorus, carbon, and silicon, present presumably in combination with iron, a considerable portion of these elements is present in a readily soluble form, and this is attributed to the "ground-mass" of the alloy. It has been attempted to show that the reaction which takes place on dissolving iron carbide alloys in acid is analogous to the process which takes place when an organic substance is subjected by steam to destructive distillation, and that the resulting compounds consist mainly of hydrocarbons and carbon compounds and small quantities of nitrogen, sulphur, and phosphorus compounds. The assumption therefore of a large number of compounds differing in their action with reagents is unnecessary.—A. W.

Iron, Rate of Diffusion of Carbon in. W. C. Roberts-Austen. Iron and Steel Institute, Spring Meeting, 1896. The Ironmonger, 281, 282.

Is a verbal statement, after instancing the kernel roasting of pyrites and the migration of platinum and gold through lead heated below its melting point, as examples of the movement of particles of solids and drawing attention to the similarity of this movement to the process of diffusion of common salt in water or in jelly at ordinary temperatures, the author pointed out that the carburising of iron might be regarded as a parallel case of diffusion. A piece of electro-iron carburised from one end by a diamond by Osmund, showed all the stages of diffusion from the carbide of iron to the pure unchanged iron. In Harveyised plates the carbon has been observed to penetrate in a similar manner, the curves of penetration being comparable with the curves of diffusion of gold in tin or lead, of platinum in lead, and of salt in jelly or water.—A. W.

Steel, Hardening of. H. M. Howe and A. Sauveur. Iron and Steel Institute, Spring Meeting, 1896. The Ironmonger, 289—293; with notes on the same by F. Osmund, The Ironmonger, 293—295.

THE first-named authors give the results of further microscopical examination of bars of the same low-carbon steel heated to the same high temperature and cooled slowly to certain points in the critical range and suddenly quenched. The changes in the carbon and iron are discussed and also the changes in the physical condition of the various carbides themselves, and suggestions are offered to account for the discrepancies between structural changes and physical properties. They think the retardations and their accompanying phenomena are due primarily to changes in the nature of the iron itself, which therefore are the real causes of the structural changes, and the changes in carbon condition, tenacity, hardness, &c.

M. Osmund states that recent researches tend to establish a parallelism between nickel, manganese, and carbon steels. In each series there are to be found—(1) a group of steels which are soft, magnetic, and are not polar-magnetic or hardly so when the metal is in the form of short bars; (2) a group of steels which are either absolutely or relatively hard, are magnetic and polar-magnetic; and (3) a group, or the representative of a group of steels, which are difficult to work in the cold, do not possess much mineralogical hardness, and are extensible and non-magnetic.

The metals of the first group have well defined and perfect critical points, which occur above 400°; the bulk of the iron is in the α state.

The metals of the third group do not possess the transformation point at all; the iron then is present in the γ form. It is suggested that it may ultimately be necessary to divide the γ modification into two. The existence of iron in an allotropic form in non-magnetic steels is considered as fully established. As regards the second group, that of the hard and polar-magnetic steels, their characteristic properties are attributed to the maintenance of a part of the iron in the β form, inasmuch as experiments show that in the case of metals of this group the transformations

take place below 350° or 400°; that is to say, below the temperature at which tempering obliterates in carbon steels the greater parts of the effects of hardening, under which conditions it is presumed the transformations of iron are incomplete. But experimental data in support of this presumption are necessarily imperfect owing to insurmountable difficulties. Yet it is thought that the facts are already capable of being grouped in a satisfactory way, and that the distinction established between γ and β iron, which is not an arbitrary, but an experimental one, will cause the difficulties to disappear which, at the outset, left a certain amount of confusion existing between the two varieties. This grouping of facts also removes the difficulties which were ushered in by the more complete knowledge of manganese steels and by the discovery of nickel steels.

While speaking in favour of Howe's carbo-allotropic theory M. Osmund thinks it may be necessary to introduce a separate theory for each substance, such, for instance, as a nickel-allotropic and a manganese-allotropic theory.—A. W.

"Pickling" in the Wire-drawing Industry. A. Menrice. Bull. de l'Assoc. Belge des Chimistes, 9, [11—12], 343—358.

To remove the coating of oxide formed on the iron rods during their passage through the rolling mill, the coiled rods are immersed in a "pickling" solution containing from 12 to 16 kilos. of sulphuric acid in 1,500 litres of water at an initial temperature of 100° C. After about two hours' exposure, during which time the bath temperature will have fallen to about 40° C., the rods are removed, washed, dried, coppered by immersion in a bath of copper sulphate, and transferred to the drawing mill.

The quality of the acid is found to have considerable influence on the ultimate condition of the wire, as well as on its behaviour in the operations subsequent to the "pickling." Testing a sulphuric acid (A) characterised as good, and a second one (B) which proved less satisfactory, the author found that the most striking difference in their constitution appeared to lie in their content of arsenious oxide, of which the good acid contained 5.8072 grms. per litre, whereas the inferior quality had only 1.2825 grm. per litre.

In practice, the acid A attacks the coating of oxide regularly, without effervescence, and the "pickled" wire has a uniform bluish-grey colour, is soft to handle, takes the copper well, and makes a wire of even gauge, without breaking in the mill. On the other hand, the bath liquor composed of the acid B gives off much malodorous gas during the pickling process, and the wire is white, rough, rusts quickly on exposure to the air, does not take the copper evenly, and when passed through the drawing mill is irregular and loses its tenacity, exhibiting a decided tendency to break. Furthermore, it wears out the face of the drawing-plate in one-seventh the time taken by the wires pickled with the acid A.

An examination of the surface of the wire from these two baths revealed the presence of arsenic on both, but that from the A acid amounted to 0.33 per cent. of the filings, whilst the proportion from the filings in the other case was only 0.15 per cent. This deposition of arsenic is believed to afford an explanation of the different action of the two baths. In the arsenical acid liquor, for example, the coating of oxide is loosened by the solvent action of the acid, but the metallic surface becomes quickly covered by a deposit of arsenic, probably as the result of galvanic action, and is not attacked by the acid. Consequently there is a considerable saving of acid, and, moreover, the coating of arsenic on the wire protects it from oxidation and facilitates the deposition of the copper. Where, however, the proportion of arsenic is insufficient to provide this protective coating, the acid continues to attack the iron in all the exposed places, with the results already signalled, the percentage of arsenic being still further reduced by the evolution of hydrogen arsenide formed during the reaction.

The most favourable proportion of arsenic for the satisfactory performance of the pickling process is 7 centigrams. per litre of bath liquor, preferably added as sodium arsenite. By this means the action and product of the bath B were

raised to the same standard as those of the acid A, the wire taking the copper and drawing equally well without more than usual injury to the drawplate.

From laboratory experiments made with oxidised and scraped iron wire, the evolved gases being absorbed by bromine, it appears that the presence of the coating of oxide economises both the acid and arsenic in the solution.

The economy of acid effected by the suitable addition of arsenic to the baths is said to amount to 50 per cent.

—C. S.

Copper and Zinc Alloys, On the Structure and Constitution of. G. Charpy. Comptes rend. 122, 670—672.

Alloys containing not more than 34 or 35 per cent. of zinc are entirely made up of a network of needle-shaped crystals. Above 35 per cent. of zinc, the crystals do not fill the whole mass, but are embedded in a glassy magma. The crystals become fewer as the proportion of zinc is further increased, until, when the zinc reaches 67 per cent., a homogeneous substance with a conchoidal fracture is obtained. These facts explain certain known mechanical properties of such alloys. Thus, in the brasses of commerce containing less than 35 per cent. of zinc, small quantities of lead and tin form, as it were, a solder between the crystals, this solder being strong at low temperatures but weak when the metal is heated above 200° C. When there is more than 40 per cent. of zinc, the lead and tin are embedded in the vitreous magma and do not weaken the structure, which explains the fact that brasses containing from 35 to 40 per cent. of zinc can be worked hot. The author is of opinion that alloys containing up to 34.5 per cent. of zinc are isomorphous mixtures of copper and of the compound Cu₂Zn, alloys containing from 34.5 to 67.3 per cent. of zinc are mixtures of Cu₂Zn, a malleable substance, and of CuZn, a hard and brittle substance; and, finally, alloys containing more than 67.3 per cent. of zinc would be mixtures of zinc with the compound CuZn.—V. C.

Alloys of Copper and Zinc. Discussion on Charpy's Mémoire. Bull. de la Soc. d'Encouragement, 1896, April, 564—570. (Compare this Journal, 1896, 117.)

A. LE CHATELIER finds that there is a limit to the increase of strength obtained by the cold working of pure metals or of those containing less than 1 to 2 per cent. of impurities. Thus the strength of an annealed copper wire, 1 mm. in diameter, was raised (by a diminishing increment) after each passage through a draw-plate without further annealing, from 25 kilos. to 51 kilos. per sq. mm. at which strength it remained constant. The strength of nickel was similarly raised from 55 to 105 kilos., at which it was constant; that of aluminium, from 12 to 25; of silver, from 18 to 33; and of cadmium, from 2.5 to 5 kilos. For all metals examined, excepting silver, the maximum strength after cold-working is double that of the perfectly annealed specimens. The maximum limit is raised by the presence of impurities, silver with 1 per cent. of Sn, breaking finally at 45 kilos. and with 1 per cent. of Cu at 55 kilos. instead of 33 kilos. In the case of alloys, some (e.g., brass, which may be drawn down indefinitely without annealing) follow the same law as pure metals; others, such as bronze, copper-silver alloys, and aluminium bronze, become more and more brittle after each successive draw without annealing, and the strength increases regularly, but at last the metal becomes too brittle to be further worked, and gives way.

In regard to annealing, five laws are formulated as the result of experiments. (1.) Annealing is never instantaneous: its effects, rapid at first, become more and more slow, and the softening tends towards a limit for each temperature. (2.) This limit is lower and is attained more rapidly, as the annealing temperature is raised. (3.) Above a certain temperature annealing is complete, and a further increase of temperature does not diminish the strength, but a crystallisation due to annealing occurs, and increases with the time of annealing, ultimately reducing the tensile strength and elongation to those of the cast metal. (4.) The presence of impurities retards the action of annealing, and demands a higher temperature for its completion. (5.) The crystallisation from annealing is due

to the presence of impurities which have lower fusing points than the metal itself, or which form compounds which have these properties.

Cold-worked metals tend to recover their malleability even at ordinary temperatures by a process which Le Chatelier terms *spontaneous annealing* (*recuit spontané*) and copper or silver wire may lose 3 to 4 kilos. of its tensile strength after merely remaining at the normal temperature for a few hours after drawing. This observation explains the phenomena of cold-working. The maximum limit of strength attainable by cold-working is reached at the moment when the increase produced by continued working is just balanced by the diminution due to spontaneous annealing. Similarly, in wire drawing, if the thickness of the metal be reduced too rapidly by successive passes without annealing, it will break owing to the failure of the spontaneous annealing to keep pace with the distorting force; but the metal may be fractured even in course of a very gradual reduction, unless it be allowed to remain at rest for 5 or 10 minutes between the passes; with this precaution, however, it may be drawn down indefinitely even without heating. Spontaneous annealing affects the mechanical properties of metals under test, causing the breaking load at any given temperature to be greater in proportion to the rapidity with which the stress is applied, whilst the deformation produced is not instantaneous, but increases more and more slowly up to a certain limit. A specimen of zinc, for example, which could support a load of 20 kilos. per sq. mm. for 2 or 3 minutes, broke under a stress of 6 kilos. at the end of 11 minutes, whilst elongating steadily up to an extension of 173 per cent. at the moment of rupture. In replying to the discussion, Charpy calls attention especially to the fact that although metals of which the fracture is crystalline may be brittle and inferior, those which show a crystalline structure under the microscope are ductile and satisfactory.—W. G. M.

Nickel and Aluminium as Minor Currency. Eng. and Mining J., June 6, 1896, 539.

EXPERIMENTS regarding the use of pure nickel, aluminium, or other substances for minor coins of the United States, and their relative adaptability for the purpose of coinage, are being made at the Mint. The United States Minister at Vienna has made a report regarding the operations of the new coinage system in Austria-Hungary, which went into operation with the laws providing for the gold standard in 1892. Austria-Hungary began the coinage of minor coins composed of pure nickel in October 1892. Regarding the success of the Austrian Mint, the United States Minister made the following statement:—

"The director and chief engineer of the Austrian Mint states that pure nickel for minor coins has many advantages. It does not change colour, it is very hard and wears very well, yet it receives a beautiful, clear impression, works well in the presses, does not oxidise, is strongly magnetic, and is superior to every other metal or combination of metals for minor coinage. The only possible objection to it which has been found in Austria-Hungary is that sometimes during the process of milling the edges of pure nickel coins nickel dust is formed in the coining ring, which adheres to the coins and sometimes dulls their brilliant surface. For this reason the authorities of the United States Mint advise that minor coins of pure nickel should have smooth edges. The composition of pure nickel as used for minor coins in Austria-Hungary is as follows:—Nickel, 97.37 per cent.; cobalt, 1.30 per cent.; copper, 0.32 per cent.; iron, 0.80 per cent.; carbon, 0.07 per cent. Excess of cobalt darkens the colour. Excess of iron and cobalt makes the metal too brittle. The plates from which the pieces are coined must be exposed beforehand to white heat for annealing in closed furnaces in order to make them sufficiently soft."

The Austrian Government makes no effort to apportion the amount of metal in the coins to their face value, but makes the lower pieces of comparatively higher value in order to make them large enough for convenient circulation. The Austrian Mint has made some coins for Serbia containing 25 per cent. nickel and 75 per cent. copper, but the Minister reports that "this composition does not receive so good or so clear an impression as the pure nickel; it soon

wears smooth, loses its bright colour, is not at all magnetic, and does not work any easier or more advantageously in the presses."

Platinum, Fusibility of, in Coke Blast Furnaces.

V. Meyer. Ber. 29, 1896, 850—852.

THE author formed two cavities in a block of fireclay and placed in one a piece of platinum foil whilst into the other he introduced a piece of foil consisting of an alloy of 25 per cent. of iridium, and 5 per cent. of platinum. The cavities were then roofed over with more of the fireclay and the block heated in a furnace provided with a powerful blast. The combustible material used in the furnace was retort graphite powdered into pieces the size of a hazel nut. Carbon and the products of combustion being very perfectly excluded in this way, the author has succeeded in melting the platinum foil whilst the iridium alloy was quite unchanged.—J. S.

Aluminium and Silicon, Some Metallurgical Applications of. H. Le Chatelier. Bull. de la Soc. d'Encouragement. Nov. 1895, 119, 1196—1202.

ALTHOUGH aluminium remains without important applications in the metallic state, it now fulfils an important part in metallurgical processes, since it is an energetic reducer, is less volatile than sodium and does not oxidise in damp air. The slowness with which it combines with oxygen under normal conditions, which may be attributed to the infusibility and insolubility of its oxide, disappears at high temperatures and when the metal is alloyed. This powerful oxidation can be utilised either in removing the small amount of oxygen taken up by metals such as iron, melted in contact with the air, or in the extraction of those metals from their oxides, which carbon fails to completely reduce. It now partly replaces manganese in the manufacture of iron and steel, wholly replaces magnesium in the making of nickel, and is used in the production of brass. In the case of iron manufacture, it is difficult to understand *a priori*, why a change from ferric oxide to alumina should improve the quality of the metal, and it is supposed that a molten metal dissolves its own sulphide, oxide, &c., and that at the moment of solidification these crystallise out throughout the mass of the metal, whereas, if the oxide, sulphide, &c. of a foreign metal be present, they are insoluble and pass into the slag. Most of the aluminium manufactured, is to-day used up in this way.

It has only quite recently been employed to reduce metals from their ores where carbon fails. Green and Wahl have used it in the preparation of manganese, and latterly they have employed it in extracting several metals. Carbon can only reduce manganese to Mn_2C containing 6 per cent. of carbon. By the use of aluminium a metal was obtained which only contained 1 to 2 per cent. of silicon, and about as much iron, which were derived from the impurities of the materials employed. The crucible used was non-siliceous, of magnesia or of earth well lined with magnesia. The mixture employed was manganese protoxide, 68; aluminium, 12; fluor spar, 10; quicklime, 10. The aluminium was powdered. The lime retained the silica and prevented the slag from becoming too fluid, and thus allowing the aluminium to float up to the surface before the reaction was complete. The crucible was heated to 1200°. The reaction was energetic and sufficient heat was evolved to melt the manganese, which was found in a button. The yield was more than 90 per cent. of the theoretical. Hadfield has used aluminium in obtaining absolutely pure iron, containing 99.8 per cent. of the metal, employing a similar mixture. Roberts-Austen has also obtained chromium by the same method and M. Vautier has reduced the oxides of sodium, potassium, calcium, and barium. With easily reducible oxides the reaction is explosive.

Moissan suggests a practical method of utilising this process in the incorporation of the elements, tungsten, molybdenum, uranium, vanadium, titanium, silicon, and boron which are difficult to reduce or fuse into the metals, iron, steel, copper, and the useful alloys. He reduces the oxide of the desired element by means of aluminium, forming an alloy of the metal with aluminium which fuses even at

the heat of the reaction. This alloy is added to the iron, steel, or copper when molten and the excess of aluminium removed by refining with oxide of iron or copper as the case may be. This method is easier, and has the advantage that the presence of the excess of aluminium aids in refining the iron, steel, or copper.

Silicon, though its heat of oxidation is lower than that of aluminium, reduces a great number of other oxides. Green and Wahl have substituted ferro-silicon for aluminium in the preparation of alloys of iron with manganese, chromium, nickel, molybdenum, and tungsten. It has, besides other advantages, that of producing an alloy containing but little carbon. Riley has shown that the percentage of carbon decreases as the amount of silicon increases. In conclusion, it seems that the alloys of silicon, and of aluminium behave in the same way. A certain excess of the metal employed must always remain in the casting and modify the properties of the pure metal.—A. W.

Metals, Behaviour of, at Abnormally Low Temperatures. Berg. u. hüttenm. Zeit. 1896, 55, 113.

STEINER found that the extension at the yield point was increased, whilst the breaking load was diminished by cooling to $-70^{\circ}C$, and that the influence was greater in the case of ingot iron than in that of weld iron. But under bending stress the influence was most clearly seen at flawed places, many samples being as brittle as glass. Dewar found that iron wire, as well as tin, lead, solder, and Wood's alloy had a higher tenacity at $-182^{\circ}C$. than at $+15^{\circ}$, whilst at this low temperature the strength of mercury is identical with that of bismuth and antimony. The strength of zinc, bismuth, and antimony decreases in the cold by 50 per cent. Tin and lead are equally extensible at normal temperatures, but at -182° tin breaks almost without elongation, whilst the ductility of lead is almost unimpaired. By alternate cooling and reheating, the magnetic properties of steel alter greatly, but a constant point is finally reached, all samples showing an increase of from 30 to 50 per cent. in the magnetic moment at $-182^{\circ}C$.—W. G. M.

Gold Ores, Roasted: Treatment of, by Means of Bromine. R. W. Lodge. Technolog. Quart. 1895, 8, 378.

THE author states that bromine seems to have the following advantages over chlorine:—

A much higher percentage is extracted, the results being estimated not only on the assay of the tailings, but also on the actual gold recovered.

The solutions obtained are much more free from base metals.

Less time is required, and the ease in using and handling bromine is much greater.

The least amount of bromine required for a successful extraction in the author's experiments was 0.3 per cent., or 6 lb. per ton. As bromine costs 25—40 cents per lb., this would make the cost very high; but with chlorine the cost would be still higher, as it is necessary to use as much as 10 per cent. of chloride of lime and 6 per cent. of sulphuric acid for even a fair extraction.—A. S.

Gold Ores, An Improved Process of Extracting. W. M. Grosvenor. Eng. and Mining J. 1896, 61, 424.

THE improved process is one combining the advantages of the stamp mill, the cyanide or chlorination, and the Siemens-Halske processes. The novel features are a mill acting as a pulveriser, amalgamator, extraction vat, and electrolytic bath combined, and a "dolly-tub" to further amalgamate the pulp and electrolyse the solution, and to allow further time for leaching.

The action in both mill and "dolly-tub" is continuous, and as only the most finely-divided gold is left for solution, larger particles being amalgamated, a single "dolly-tub" usually gives at least 90 per cent. complete extraction.

As a stamp mill the plant shows great efficiency and durability. A plant requiring a 20-h.p. engine will crush over a surface of about 200,000 sq. in. per minute.

Ore has been treated at a cost of about 1.50 dol. per ton with coal costing 5.50 dols. per ton in a rough experimental

plant. It is claimed that with four 25-ton mills, a modern engine and boiler, and coal at 3.50 dol. to 4 dol. per ton, extraction would cost less than 1 dol. per ton, whilst with water power, the cost could be reduced to about 70 cents.

—A. S.

Cyanide Process, The, as Applied to the Concentrates from a Nova Scotia Gold Ore [Arsenical]. R. W. Lodge. *Techn. Quarterly*, 8, 339.

The author refers to the experiments of W. A. Tucker with the cyanide process, on a gold ore containing a large amount of arsenic.

The ore contained free gold and about 12 per cent. of sulphides, and the concentrates obtained from it contained about 66.5 per cent. of arsenical pyrites.

The percentage of gold extracted from the concentrates (passed through a 30-mesh sieve) by the cyanide process varied from 51.84 per cent. to 93.68 per cent., according to the manner and duration of the extraction.

These experiments seem to show that the presence of arsenic does not materially affect the cyanide process.

If the extraction be performed in closed vessels, the consumption of potassium cyanide is lessened, also the extraction is increased, thus contradicting Elsner's equation in which oxygen is necessary. Agitation of the ore, and solution, increased the amount extracted, although such is not generally the case in actual practice.—A. S.

Gold Extraction in Cyanide Works [Sources of Error and Loss]. W. A. Caldecott. *Standard and Diggers' News*, Johannesburg, April 25, 1896, 19.

The author gives his opinion from facts observed as to the discrepancy between the actual and theoretical yield of gold by the cyanide process.

With fresh zinc or amalgamated copper plates, a little gold is lost by remaining on the plates. Errors may also occur in the calculation of the tonnage of tailings. Another source of error occurs in the attempt to obtain representative samples of the tailings. The best way is to take one with a sampling-rod from each truck, and then quarter down in the usual way.

A serious error often occurs through the leakage of gold-bearing solutions, owing to imperfect construction of the leaching vats. The author suggests that soluble cellulose might perhaps be applied as a waterproof lining for the vats.

Loss often occurs by gold slimes, after precipitation, being mechanically carried on into the sumps by the force of the current in the extractors. This may be obviated by using more extractors, or by adopting a lower speed of solution. Also some finely-divided gold may pass through the filters used for draining the gold slimes; it is advisable therefore to run all solutions from the zinc boxes into a settling vat to allow the gold to deposit.

Some gold may be left behind in slags, but this may be brought down to a very small amount by the proper adjustment of fluxes.—A. S.

Cyanide Process: Notes on the Treatment of Zinc-box Precipitate (Slimes) from, as practised at the Standard Consolidated Mines, Bodie, California. R. G. Brown. *Inst. Mining and Met.*, May 20, 1896.

In view of the position, more commonly taken of late, that the sulphuric acid treatment of zinc-box precipitate ("slimes") leads to large losses, the following notes are considered interesting:—

The slimes are filter-pressed, the effluent giving no more than the faintest sign of sediment after 24 hours, the average amount of gold present being valued at only 2½ d. per ton of solution; and since 1,000 oz. of precipitate are washed by 2½ tons of water, this loss is inconsiderable. The cakes are dried on an iron pan placed in a rectangular brick furnace with an iron top, and provided with a hood and stove-pipe flue. Working upon 4,400 oz. of precipitate the loss was only 0.03 per cent. Several pounds of mercury were recovered from the flue during the year. With every ounce of bullion, 1.1 oz.

of slag was produced, containing gold to silver in the ratio of 1:6.5, whilst the corresponding ratio in the bullion was 1:2.9. Fluxes were used to the amount of one-quarter of the precipitate by weight, and consisted of borax 4 parts, sand 2 parts, soda 2 parts, and nitre 1 part. The consumption of cyanide and of zinc per ounce of precious metals recovered was 0.52 lb. and 0.31 lb. respectively during a run of eight months.—W. G. M.

PATENTS.

Steel Wire, Improvements in the Method of and Apparatus for Hardening, Tempering, and Timing. J. H. Roberts and J. Cooper, Bradford. *Eng. Pat.* 7904, April 20, 1895.

The wire is heated in the ordinary way by passing it through heated tubes; thence it passes through an air-tight chamber provided with a glass window, through which the wire may be examined to see whether it has acquired the proper temperature, before entering the hardening bath. This latter consists of a shallow trough, through which the hardening liquor is made to flow in a continuous current. On leaving this bath the wire passes between strips of "card-cloth," and is thus wiped dry before entering the tempering bath. A cooling chamber, through which a continuous current of air is made to pass, is interposed between this latter and the pickling bath.—J. H. C.

Gold and Silver from their Ores, Improvements in and relating to the Extraction of. A. Schmidt, Berlin. *Eng. Pat.* 8376, April 27, 1895.

CYANIDE of an alkali metal is employed as a solvent in the ordinary way, but its action is accelerated by the addition of a small proportion, usually 1 to 5 per cent. of an organic nitro- or nitroso-compound. Commonly an addition of hydrate or carbonate of an alkali or alkaline earth is also made amounting to about 20 per cent. of the quantity of nitro-compound present.—J. H. C.

Gold-bearing Antimony Ores, An Improved Process for the Treatment of. J. J. Christmas, Adelaide, South Australia. *Eng. Pat.* 10,399, May 27, 1895.

ABOUT 25 per cent. of melted lead at a low temperature and with or without fluxes or reducing agents is added to the melted antimony. After stirring, the molten mixture is run into moulds and "packed" by tapping while cooling, after which the lead containing the gold is found beneath the antimony and can be separated from it by a smart blow.—J. H. C.

Gold or Silver, or both, Improved Process and Apparatus for Treating Ores and Liquids Containing. A. de C. Scott, London. *Eng. Pat.* 12,102, June 21, 1895.

The solvent liquor (such as cyanide of potassium) is injected into the crushed ore or slime under pressure in apparatus as described, periods of rest being allowed in order to limit the consumption of the solvent and to give time for its proper action on the ore, after which the clear solvent is decanted for further use until it has become sufficiently strong for precipitation in the ordinary way by zinc turnings.

—J. H. C.

Furnaces, Improvements in. J. Gjers, Middlesboro'-on-Tees. *Eng. Pat.* 10,815, May 31, 1895.

The furnace is constructed with a closed combustion chamber provided with a grate on which the fuel is burnt, and a closed ashpit with water bottom; heated air is supplied above the fuel, while water vapour is made to ascend through it from below, by which means additional combustible gases are produced.—J. H. C.

Furnaces, Improvements in. A. M. Hewlett, Kewness, Ill., U.S.A. Eng. Pat. 16,297, Aug. 30, 1895.

See under I., page 338.

Zinc, Lead, and Silver, Improvements in and relating to the Treatment of Ores or Materials Containing. C. Hoepfner, Giessen, Germany. Eng. Pat. 8328, April 26, 1896.

Ores containing the sulphides of lead and zinc are powdered and treated in a stirring vessel with a solution of free chlorine, of perchloride of iron, or of a mixture of cupric chloride and sodium chloride at a moderate temperature, so as to dissolve only the lead with any silver that may be present. The residue containing the zinc may be treated for its recovery in any known way, the gold, if present, having been previously extracted by means of free chlorine or by cyanide, after roasting.

The silver is separated from the solution electrolytically or by means of finely divided copper or lead. The copper (if present) is also separated electrolytically or by precipitation, after which the chloride of lead which separates on cooling may be utilised as such or converted into other lead compounds, or into metallic lead.—J. H. C.

XI.—ELECTRO-CHEMISTRY AND ELECTRO-METALLURGY.

(A.)—ELECTRO-CHEMISTRY.

Spent Molasses [Strontia and Lime Processes], Electrolysis of: Influence on the Composition of the Ash. Zeits. f. Elektrochem. 1896, 573.

See under XVI., page 463.

PATENTS.

Secondary or Storage Batteries, Improvements in [Aluminium Supports]. L. Falero and H. Lumley, London. Eng. Pat. 10,448, May 27, 1895.

THE improved electrodes consist of receptacles or vessels made of aluminium gauze or tulle, or a perforated sheet of aluminium or its alloys, containing the active material, which preferably consists of a paste made of litharge. These electrodes are provided with one or more central metallic conductors, which latter may be of the same material as the receptacle, and moulded in any desired form.—G. H. R.

Diaphragms or Partitions for Electrolytic Purposes formed of Carbonates of Alkaline Earths. S. S. Bromhead, London. From La Société Anonyme des Anciennes Salines Domaniales de l'Est Actien Gesellschaft, Bieuzee, Germany. Eng. Pat. 23,852, Dec. 12, 1895.

THE diaphragms are manufactured preferably from naturally-occurring carbonates of the alkaline earths, but those artificially prepared may also be employed. For instance, they may be produced from limestone blocks by cutting them into the form of plates, tubes, pots, boxes, or the like, or the diaphragms may be prepared under pressure from a moistened mixture of pulverised limestone and calcined magnesite.—G. H. R.

Alkali-Amalgam obtained in Electrolytic Apparatus, Improvement in the Method and Apparatus for Washing. P. Jensen, London. From H. C. F. Störmer, Christiania, Norway. Eng. Pat. 24,837, Dec. 27, 1895.

A SUITABLE receptacle containing a shallow perforated box or cup is connected with suitable mechanism for lifting it up and down. Inlet and outlet pipes are provided for the amalgam and washing liquid respectively, and a series of receptacles may be arranged in such a way that the amalgam and wash liquid pass through them in opposite directions. When the rod is depressed, the box fills with the amalgam, which falls through the perforations in fine streams when the box is raised, thus exposing a large surface to the action of the washing liquid. The action of the apparatus may be improved by arranging in the bottom

of the receptacle rods of any suitable material, as iron wire or ebonite, of a thickness of one-eighth to quarter of an inch, the rods passing through the holes in the cup, so that there only remains a narrow annular space for the amalgam to fall down through. The surface of amalgam exposed to the water is thus greatly increased.—G. H. R.

Electric Battery, An Improved, and Method or Process of converting the Potential Energy of Carbon or Carbonaceous Materials into Electrical Energy. W. W. Jacques, Newton, Massachusetts, U.S.A. Eng. Pat. 4788, March 3, 1896.

THE battery consists of an iron vessel forming the cathode, closed by a non-conducting lid, from which the carbon anode is suspended. Pipes are provided for the admission and withdrawal of the electrolyte, and for the escape of gases formed in working. The electrolyte is fused sodium or potassium hydrate, which is maintained at a temperature of about 400° to 500° C. by means of a furnace surrounding the vessel, and the electrolyte is kept in a state of violent ebullition, and constantly supersaturated with oxygen by means of air passed into it under pressure through a finely perforated rose. It is claimed that the addition of a small quantity of magnesium oxide greatly diminishes the formation of carbonate.—G. H. R.

Electrolytic Processes and Apparatus therefor, Improvements in. G. B. Baldo, Trieste, Austria. Eng. Pat. 5098, March 6, 1896.

THE apparatus is an improvement on that described in Eng. Pat. 18,406, 1895 (this Journal, 1896, 204 and 198), and consists of an outer vessel which contains a porous cell forming the cathode, inside of which is a second porous vessel containing the anodes, which are of carbon or other suitable material. The cathode, which is provided with a flange which forms a lid to the outer vessel, is constructed of an open or skeleton framework of earthenware or the like material, which is covered with linen, and surrounded by a layer of asbestos board about 1 mm. in thickness, which again is surrounded and is in contact with an open-work metal sheet, such as close wire netting. The inner porous vessel is similarly constructed, with the exception that it is covered with an outer layer of linen instead of a metal sheet. This vessel is closed with a cover, and both it and the containing vessel are provided with an inlet pipe for the liquid and an outlet pipe for the gases, and all three divisions of the tank have pipes by which their contents may be drawn off. When the apparatus is employed for the electrolysis of sea water, the outer vessel is filled with fresh water and the two inner divisions with sea water. On the passage of the current, hydrogen is given off at the cathode and chlorine at the anode, while filtered caustic soda solution is produced in the outer vessel, and the oxides of calcium and magnesium are deposited in the space intervening between the cathode and the inner porous vessel. The liquid in the inner vessel contains free sulphuric acid produced by the decomposition of sulphates contained in the sea water, together with undecomposed sodium chloride and other salts.—G. H. R.

Ozone, Improvements in and Apparatus for the Manufacture or Production of. M. Otto, Paris, France. Eng. Pat. 5195, March 7, 1896.

THE improved apparatus comprises a number of elements each consisting of a conducting sheet, which may be plain or in the form of a grating, but the corners of which must be rounded off. Each sheet is placed between two plates of glass or other dielectric, and the elements so formed are enclosed in a casing, and separated from each other, so as to allow the gases to be treated to pass between them. The alternate elements are connected together and to the opposite terminals of a high-tension transformer. By suitably choosing the dimensions of the constituent elements of the apparatus, it may be made to act as a resonator, and give an oscillatory discharge, which is stated to give the highest yield of ozone. This condition is satisfied when the ratio between the co-efficient of self-induction L of the apparatus,

and its electrical capacity, C , is such that the resistance of the system is less than $\sqrt{\frac{4L}{C}}$. With an apparatus having glass sheets 0.40 m. long, 0.16 m. wide, and 0.001 m. thick, with sheets of conducting metal 0.27 m. long, 0.05 m. wide, and 0.0001 m. thick, the elements being arranged at a distance of 0.0015 m. apart, and the apparatus being supplied with a current having a periodicity of 80 per second and a tension of 5,700 volts, the power consumed in full operation is 10 watts. The yield in ozone is stated to be considerable, and to be obtained at a low cost.—G. H. R.

Electric Furnaces, Improvements in [Liquid Forge].
G. D. Burton, Boston, U.S.A. Eng. Pat. 7712, April 17, 1895.

In this apparatus the metal is fused, or the ore is smelted by means of an electric arc sprung between the metal or ore and an electric bath. The bath is contained in a tank constructed of or lined with a non-conducting material, and divided into three compartments by a vertical transverse partition near one end and a longitudinal partition near one side. These partitions are perforated below the surface of the liquid, or may be formed of a reticulated screen of any non-conducting material. The bath is composed of an electrolyte having a density greater than water, and capable of evolving hydrogen and of forming an electric arc with the metal to be heated. For small work, the bath preferably consists of a chloride of sodium solution of a density of 1.050, but for larger work the density of the solution and its composition may be varied. The anode, which is preferably in the form of a serpentine plate of lead, is placed in the transverse compartment, and is connected at one end with a copper conductor which rises through the cover, and is suitably connected with the positive lead from the source of electric supply. The hearth is composed of fireclay, perforated through its depth. A pump placed in the longitudinal compartment enables the level of the liquid in the hearth compartment to be raised into or out of contact with the work placed on the hearth. A bar of copper or other suitable conductive metal is connected with the negative pole, and forms a rest on which the implement grasping the article to be heated may make contact for closing the circuit. A conductive sliding rod, properly insulated, brings one end into contact with the terminal. An electrode provided with an insulated handle is hinged to this rod, and is adapted to make contact with the work on the hearth. An automatic electrode similar to the above, is hinged directly to the negative terminal of the bar.

—G. H. R.

Electric Furnaces, Improvements in [Liquid Forge].
G. D. Burton, Boston, U.S.A. Eng. Pat. 7713, April 17, 1895.

THE liquid forge consists of a tank constructed of or lined with a non-conducting material, which contains the electrolytic bath. This vessel is divided into a plunger compartment, a hearth compartment, and an anode compartment, by two perforated partitions, one of which is placed longitudinally near one side. The bath partially fills the vessel, and is composed of an electrolyte having a greater density than water, and capable of evolving hydrogen and of forming an electric arc with the metal to be heated. For small work the bath preferably consists of a chloride of sodium solution of a density of 1.050, but the density must be increased proportionately with the size of the work. The anode is a plate of lead connected with a copper rod which is in contact with the positive pole of the source of electric supply. The hearth, which is formed of fireclay or other non-conducting material, is divided into two portions, one of which is fixed in a recess in the bottom of the bath,

while the other portion is supported on a slide, so that it can be moved to or from the other portion of the hearth. A gauge and pointer are provided so that the movement can be regulated. By means of a lever the liquid in the hearth compartment can be forced into or out of contact with the metal placed on the divided hearth. A copper bar connected with the negative terminal of the source of electric supply is supported on the front side of the tank on insulated studs. This bar serves as a rest on which the tool for grasping the article to be heated may form contact for closing the circuit. When it is desired to heat a piece of metal, the latter is laid with its two ends resting on the opposite portions of the divided hearth, the negative electrode is connected with the metal, and the level of the liquid in the hearth chamber is raised into contact with the metal, thus closing the circuit. Hydrogen is evolved from the electrolyte, and forms a film between the work and the liquid, and causes an arc to be struck which heats the former.—G. H. R.

Metals or Metallic Alloys by Electrolysis, An Improved Method or Process for obtaining. E. Jordis, Munich, Germany. Eng. Pat. 11,298, June 8, 1895.

THE improvement consists in the use of lactic acid or its salts in galvanic baths, the lactic acid or its salts being used already formed, or formed by appropriate process in the bath itself. By the employment of lactate solution it is claimed that the use of cyanide of potassium may be dispensed with. As an instance of the process, a silver bath may be quoted:—1 to 3 per cent. silver of nitrate (AgNO_3), 3 to 5 per cent. of lactate of ammonium, and ammonia up to alkaline reaction.

The lactate of ammonium can be replaced, especially in nickelling, partly or wholly by lactate of potassium. Baths for depositing platinum, zinc, and nickel are also described, and a table is given of the current density to employ in the case of copper and iron, and alloys of these metals.

It is also proposed to replace, wholly or partially, the lactic acid by its homologues, especially by glycolic acid.

—G. H. R.

Electro-Plating Bath, An Improved. S. Pitt, Sutton, Surrey. From W. B. Hollingshead, East Chester, U.S.A. Eng. Pat. 5113, March 6, 1896.

THE improved bath is made as follows:—12 parts by weight of ammonium cyanide dissolved in three times its bulk of water at a temperature of 110°F. ; 61 parts by weight of potassium tartrate (neutral) dissolved in about three times its bulk of water at about 110°F. ; 27 parts of a mixture of oxide of copper and water mixed to a pasty consistence, the last two ingredients are then mixed, the potassium tartrate forming the solvent for the cupric hydrate. The ammonium cyanide is then added to the mixture and a quantity of water equal in bulk to about three times that of the other two ingredients is added to reduce the bath to a proper strength for use. The potassium tartrate may be replaced by Rochelle salt.

—G. H. R.

XII.—FATS, OILS, AND SOAP.

Wool Oils. J. Lewkowitch. J. Soc. Dyers and Col., 1896, 12, 60.

THE so-called wool oils used for lubricating the wool in wool spinning may be sub-divided into (a) fatty oils, (b) oil emulsions, (c) solutions of soap. Mineral oils by themselves are unsuitable for oiling wool, though they are largely used for the adulteration of fatty oils intended for the woollen industry. The fatty oils used are olive oil, lard oil, oleine (oleic acid), distilled grease oil, black recovered oil, "seek oil," and brown (grease) oil. The emulsion oils are chiefly aqueous solutions of soda or ammonia, containing larger or smaller proportions of oleic acid soap and mineral oils held in solution by them. The soap solutions are represented by solutions of castor oil soap, or of a neutral alkali salt of sulphorcinoleic acid. The valuation of wool oils is governed by the principle

that, as they must be easily removable in the scouring, they should not contain any drying oils or their fatty acids, nor any resin oil or resin acid. Whether mineral oils are permissible in wool oils has not been satisfactorily decided yet, some investigators fixing the practicable limit of the admixture of mineral to fatty oils at 80 per cent., others at 20 per cent., whilst others maintain that they should be altogether excluded. Wool oils should produce as little heat as possible, both in the stored raw material and during the working of the oiled material. Therefore the flash point of an oil and its liability to cause a fire or favour its spreading, are matters of the greatest importance, and the charges of fire insurance companies are in direct proportion to the quantity of unsaponifiable matter, hydrocarbons, in wool oils. The determination of the flash point and of the amount of unsaponifiable matter, are therefore most important in the analysis of wool oils. But the last-named factor should not be determined by difference as is frequently done, but should be estimated directly, as in the presence of wool grease or its distillates in wool oils, much of the unsaponifiable matter may consist of a solid alcohol (cholesterol). The flash point is determined by the open test, and the liability to spontaneous combustion in Richard's or preferably Mackey's apparatus. The objection of the insurance companies to neatfoot or tallow oil is strange, considering their approval of the certainly dangerous fish oil. Moreover, the admission of the latter renders the detection of the prohibited cotton-seed oil almost an impossibility.

In the discussion following the paper it was remarked that the elimination of mineral oils from wool in the scouring process is a very difficult matter, and that, indeed, the excess of soap required for this purpose partially neutralised the saving in the original price of the wool oil. Also fatty oils may offer considerable resistance to their removal from the fibre in the scouring process when they had had time to undergo oxidation, and for this reason, from the spinner's point of view, an oil was the more objectionable the more readily it would undergo oxidation, and the interest of the insurance companies tended in exactly the same direction, since the liability of an oil to induce spontaneous combustion was directly proportional to its readiness to undergo oxidation. Any oil possessing an iodine number of from 80 to 90 would be quite safe; if it went beyond 100 it would be absolutely useless as a wool oil, as also if the rise of temperature on mixing with sulphuric acid were considerable.—C. O. W.

Wool Grease, Composition of. L. Darmstaedter and J. Lifschütz. Ber. 29, 1896, 618—622.

THE alkaline liquid obtained from the partial saponification of wool grease was separated by the authors (this Journal, 1896, 206) into a soluble and an insoluble portion. From the latter the authors obtained two new alcohols which they propose to term "lanestols," whilst the former was divided by a process of fractional neutralisation into three distinct soaps, which have now been submitted to a closer examination. The first of these proves to be chiefly the potassium salt of carnaubic acid, whilst the second contains potassium myristate. The third fraction consists principally of foreign fatty acids, derived from the soap used in washing the wool, which constitute from 20 to 28 per cent. of commercial wool grease, together with a small quantity of myristic acid. From the properties of the above soaps and the acids resulting therefrom it appears that the carnaubic acid is identical with that described by Stürcker (Ann. d. Chem. 223, 306; this Journal, 1884, 148), and the myristic acid with those acids described by Playfair, Krafft, and Heinz. —J. S.

Lanolinum Anhydricum, Adeps Lanæ and Wool-Fat. Von Coehenhausen. Dingl. Polyt. J. 1896, 299, 256.

See under XXIV., page 480.

Colza Seeds, Adulteration of. Journal de Pharm. [6], iii., 434.

PAJOT gives a case of adulteration of colza seeds, with grains of a variety of mustard known as "snavé" and also

of *Brassica Juncea*, both being artificially treated with a coating of blue colouring matter—a kind of litmus. Maceration in water revealed the fraud, a blue solution being afforded giving with acids a rose coloration, restored to blue by alkalis. This sophistication it is alleged was carried out in Germany. The coloured seeds are far below the market value of true colza seeds, and yield 10 to 12 per cent. less oil. The oil-cake could not be honestly employed as cattle food, and the article, it is significantly added, was only fit for manure.

Cod Liver Oil. A. Jorissen. Chem. Zeit. Rep. 20, [30], 103.

ACCORDING to the Belgian, French, German, and Swiss pharmacopœias, this is the white oil derived from the fresh liver of the cod, *Gadus Morrhua*. In the Russian pharmacopœia that from the dorsch, *G. Callarias* is also official.

The author has examined the reactions given for pure cod liver oil by these different authorities, which are not, in his opinion, always in accord.

A specimen of oil prepared according to the directions of the "Codex Français" had a specific gravity of 0.929 at 15° C., while three samples obtained from different druggists in Liège gave from 0.924—0.9255. A mixture of equal parts of cod liver oil (0.929) and cotton-seed oil had a gravity of 0.9225. By the action of concentrated sulphuric acid on an oil known to be pure, the author obtained a reddish violet colour. This is given as characteristic of a pure product by the Swiss pharmacopœia. With fuming nitric acid there was a rose-red colour, which changed gradually into yellow. The oil from the liver of *Gadus Carbonarius* gave with fuming sulphuric acid a violet blue colour, soon changing to brown. Oils of different origin showed a difference in the separation of solid glycerides when exposed to cold. Some samples purchased at Liège gave no deposit, while those prepared by the author invariably did so, though the bulk of the oil remained fluid. Others again deposited so much that the oil could no longer be poured out. The refractive power of liver oils (determined by the Zeiss refractometer) was changed by the addition of vegetable oils. Variations were obtained with the different kinds of cod-liver oil in the rise of temperature with sulphuric acid. In a sample from Ostend the temperature rose to 114° C., while in three bought in Liège the rise was to 93°, 104°, and 107° C. respectively. A liver oil which showed a blue colour with nitric acid gave as the final temperature 85° C., and a mixture of equal parts of official cod-liver oil and cotton-seed oil gave 81° C.—C. A. M.

PATENT.

Soap Extract, a New or Improved, and a Process for Manufacturing the Same. A. Luhn, Ritterhausen, Barmen, Germany. Eng. Pat. 7442, April 11, 1895.

"180 parts of soda are dissolved in 300 parts of boiling water. In this solution is allowed to melt 200 parts of

pure soap having a base of turpentine and ammonia, to which is added 200 to 300 parts of dried, sifted, neutral soap. The soap thus obtained is shredded or divided into threads or filaments and mixed by continual agitation with a pulverised neutral soap in the proportion of 100 parts of the former to 200 parts of the latter, two-thirds per cent. of caustic ammonia being added thereto."—J. A.

XIII.—PIGMENTS, PAINTS; RESINS, VARNISHES; INDIA-RUBBER, Etc.

(A.)—PIGMENTS, PAINTS.

PATENT.

Pigments, Sulphate of Lead and Lead; Improvements in the Manufacture of. H. R. Gregory, London. Eng. Pat. 9891, May 18, 1895.

A mixture of galena and magnesite in equivalent proportions is roasted, treated with water and sulphuric acid for 12 hours, and the soluble matter removed. The residue is boiled for one hour with a slight excess of caustic alkali; the lead hydrate washed, dissolved in nitric acid, and precipitated again as sulphate. Other alkaline earths may be used in the roasting; but if chalk be employed, the mass requires treating with a weak solution of sodium carbonate for several days to decompose the crude sulphate of lead.

To improve the quality of the pigment 100 parts of the sulphate are boiled with about 9 parts of caustic lime or 5 parts of magnesia. The resulting substance is thoroughly washed and dried.—F. H. L.

(B.)—RESINS, VARNISHES.

Varnishes, Notes on the Drying of. L. E. Andés. Chem. Zeit. 1896, 20, 307.

By the addition of a certain limited amount of mineral oil to linseed varnish, the drying of the latter may be retarded, or even completely prevented. If, however, the adulterant be introduced in sufficient quantity, it is found that a thin film of the substance on exposure to air separates into two layers; the true varnish absorbing oxygen and drying in the usual manner, whilst the lubricating oil remains on the surface. A mixture of equal parts of linseed varnish, drying resin oil, and mineral oil behaves in a similar manner, the two former drying together and the latter separating out. A parallel result was also obtained by the addition of excess of turpentine to a spirit varnish. Experiments were tried as to the possibility of improving the working qualities of such a medium (*i.e.*, lowering the speed of its drying) by mixing in turpentine, when a point was reached at which the varnish worked better under the brush, but dried almost instantaneously, separating as before into two distinct layers, dry varnish underneath and turpentine above. When the latter had evaporated, the varnish was found to have a matt surface. Smaller amounts of turpentine may be, and often are, added to spirit varnishes without harmful results; the mixed solvents evaporating together. In the case of oil varnishes where the turpentine is adulterated with petroleum spirit, the only effect of the sophistication is to hinder the drying of the material, without influencing, however, the durability of the final product.

It is suggested that this phenomenon of separation should be employed as the basis of a method for testing the purity of any sample of linseed oil varnish.—F. H. L.

PATENTS.

Plastic Mixtures [Rubber or Horn Substitutes] or Compounds; Improvements in the Manufacture of. L. F. A. Magdolf, Berlin. Eng. Pat. 3412, Feb. 14, 1896.

A resin, such as shellac, copal, &c. is dissolved in alcohol and mixed with some insoluble material such as chalk, powdered glass, &c., the weights of the ingredients being in proportion to their respective specific gravities. The mixture is well stirred and precipitated by the addition of water; the deposit being finally dried, compressed, powdered, and melted into the desired shape.

The composition is adapted for the manufacture of buttons, door handles, and insulators.—F. H. L.

XIV.—TANNING, LEATHER, GLUE, SIZE.

The Sweating Process in the Tannery. W. Schmitz-Dumont. Dinger's polyt. Jour. 1896, 300, 139--144.

VILLON (*Traité pratique de la fabrication des cuirs et du travail des peaux*, 1889) claims to have traced the loosening of the hair in the sweating process to the putrefactive action of a specific bacterium which he styles the *bactérie pilline*; this organism is aerobic and feeds upon the hair substance (pilline), converting it into leucine, tyrosine, butyric acid, margaric acid, and ammonia; the ammonia dissolves the corium and thus swells the hide. Villon further claims that he has obtained pure cultures of this bacterium on ammoniacal gelatin—ammonia having an inhibitory effect upon other bacteria—and to have inoculated sterilised hide therewith, when an evolution of ammonia and loosening of the hair followed.

The author criticises the experiments on which Villon bases his conclusions, on the ground that the method adopted for obtaining antiseptic conditions was not sufficiently drastic. He next describes in detail some experiments which he has himself conducted with the hope of confirming Villon's results. Sterilisation of hide by exposure to a temperature of 50° C. for 24 hours, followed by 10 minutes at 110° C. (the method adopted by Villon) was found to be impossible. Recourse was therefore had to the use of antiseptics, and carbon bisulphide in the form of potassium ethyl dithiocarbonate (potassium xanthogenate) was employed as being easily removed by washing and not deleterious to the hide.

The following conclusions are drawn:—A dilute solution (1—0.25 per cent.) of potassium xanthogenate will gradually kill all micro organisms existing in hide from which the hair has not been removed, without changing the hide to a perceptible extent, even after half a year's immersion. A short exposure (24—48 hours) to this antiseptic will prevent general putrefaction, but will not destroy a streptococcus which, by decomposing the *rete malpighii*, loosens the hair. The organisms which remain active in this way evolve ammonia without any marked quantity of other odiferous compounds, and are apparently killed, before there has been any attack on the hide fibre, by the decomposition products of the *rete malpighii* cells. The identity of these micro-organisms with a known form remains to be proved; so far, a tendency of the colonies to develop in the form of an intricate and extensive net work seems to characterise this streptococcus.

It is proposed that, in the very probable event of a pure culture of the bacterium which is responsible for the loosening of the hair in the sweating process being obtained, a rational system of sterilising the hide by carbon bisulphide vapour and then inoculating it with the necessary bacterium, shall be followed by the tanner who unhairs by sweating. An apparatus for accomplishing this end is represented in the figure, in which A is a sheet-iron box suspended by a chain working over a pulley, so that the hides B may be readily placed in position. The edges of the box rest in the seal C, containing water, to which an antiseptic has

been added. The carbon bisulphide may be sprayed into the chamber by a suitable pulveriser, and may be removed when sterilisation is complete, by a current of air led in

through the pipe D, having been previously passed through a system of hot tubes, and out through the pipe E. The pure culture of the unhairing bacterium, suspended in water, is sprinkled on to the hide through the pipe F.

—A. G. B.

PATENTS.

Leather, Imitation or Artificial; Improvements in the Manufacture of. H. Schmiedel, Vienna, Austria. Eng. Pat. 8215, April 25, 1895.

A LIXEN or cotton fabric is glued on to strong paper, then painted with water colours, aniline colours, or a lacquer made of shellac dissolved in diluted borax solution, or of tannin or casein, and finally calendered and embossed by calendering and goffering rollers. The material serves for binding books and for other fancy purposes to which leather is applied.—A. G. B.

Soluble Colloids, such as Gelatin and Isinglass, Improvements in the Formation and Preparation of. E. J. Mills, Glasgow. Eng. Pat. 8847, May 4, 1895.

ACCORDING to one modification of this invention, gelatin or a gelatin containing a gelatinous substance, is heated with a solution of fixed alkali. In a short time a gelatin compound is formed which remains liquid in the cold. The proportion of alkaline material necessary, depends partly on the nature of the gelatin under treatment. A fair sample of gelatin can, in general, be permanently liquefied by heating it at 100° C. with about five times its weight of water and one-twentieth of its weight of slaked lime for two hours; in many cases a smaller proportion of water will suffice.

Another modification consists in dissolving the gelatin in about 10 times its weight of water, keeping the solution at a temperature distinctly above its setting point, and seeding it with microbes capable of permanently liquefying gelatin. *Bacillus liquificiens*, for example, succeeds well. After three days it will generally be found that the solution remains permanently liquid in the cold. The addition of a small proportion of meat extract, together with a trace of sodium carbonate, will accelerate the action of the microbes.

By either process, non-corrosive colloid products of value as gums, thickeners, detergents, emulsifiers, and media for photo-lithographic and other photographic purposes are obtained.—A. G. B.

Whalebone, Imitation; Improvements in the Manufacture of. J. Baier, London. Eng. Pat. 10,193, May 23, 1895.

SINews, muscles, guts, and other parts of animals are first thoroughly cleansed from adhering skins, and fatty or meaty parts, then soaked in soda, salt, or other preserving agent, then treated with a solution of oxide of zinc, which acts as a deodoriser, and subsequently steeped in water for one or two days. The material is then passed through a solution of sulphate of iron—say, 1 lb. of sulphate of iron to $\frac{1}{2}$ ton of the material to be treated—and subsequently immersed for a day or more in a suitable mixture, say, of $\frac{1}{2}$ lb. of carbonate of potash, 5 galls. of spirits of wine, and 10 oz. of saffron, to $\frac{1}{2}$ ton of the material, but other suitable chemicals which will give the necessary elasticity may be substituted if desired. The soaked material is dried

in suitable frames below 90° F., and cut up in the desired form. Greater elasticity may be imparted by immersion in oil, such as linseed or poppy oil, at 90°–100° F. for 48 hours.—A. G. B.

Substitute for Whalebone, A New and Improved Manufacture of a Material suitable as a. G. L. A. Kuhlmann and J. Baier, London. Eng. Pat. 2090, Jan. 29, 1895.

This specification is virtually identical with the preceding one. The substitute is called "Myoline."—A. G. B.

Whalebone, Artificial or Imitation. W. Hunkemöller, Amsterdam, Holland. Eng. Pat. 1214, Jan. 17, 1896.

THE sinews or tendons and other similar parts of oxen, buffaloes, and horses, in a fresh or salted condition, are soaked in a solution of chrome alum, to which is added chloride of sodium up to one-twentieth of the weight of the alum. After being superficially dried, the tendon is flattened out to the desired thickness and cut according to requirements. In some cases the outer membrane is detached from the oore, flattened, and cut into strips.—A. G. B.

Horn-like Material, An Improvement in the Treatment of Skins for Producing a. C. Marter and J. Levy, London. Eng. Pat. 4718, March 2, 1896.

IN addition to, or instead of, the application of linseed oil, described in Specification 1820 of 1895 (this Journal 1896, 208), other oils and oleaginous substances, such as cotton seed, rape, cocoa-nut, and other vegetable oils, also animal and fish oils, vasoline, paraffin, stearin wax, and the like, or mixtures of these, may be applied to the prepared skins.

Inoculation of Soil for the Cultivation of Leguminous Plants, Improvements relating to the. Dr. F. Nobbe and Dr. L. Hiltner, Tharand, Germany. Eng. Pat. 11,460, June 12, 1895.

THE inventors find that the nitrogen-transforming bacteria proper to the Leguminosae, and obtained by Von Beyerrinck, when introduced into soil free from the bacteria, produce, in accordance with his statements, the root nodules or tubercles on the plants having papilionaceous flowers, these growths being capable of assimilating free nitrogen. Thus, a soil containing no assimilable form of nitrogen, when inoculated with these bacteria, will produce a rich yield from the growth of Leguminosae, which plants without such inoculation would have starved.

Pure colonies of the active bacteria for the Leguminosae are obtained in agar-gelatin, with suitable additions, such as sugar, asparagin, or the green substance of the plant, placed in glass tubes. Or the bacteria can be prepared in fluid cultures. The contents of a tube are dissolved in from 1 to 3 litres of water, previously mixed with one of the named substances, and, immediately before sowing, the emulsion is poured over the seeds, the contents of three tubes sufficing for 20 kilos. of clover seeds; the whole is then mixed with sand or earth until its condition is suitable for sowing in the soil. Instead of this method, a small quantity of sand or earth may be moistened with the bacteria-charged emulsion, and, after air-drying, be worked into the soil.—E. S.

Fertilising by the Aid of Artificial Nitrogenous Manure, Improvements in. H. Mehner, Charlottenburg, Germany. Eng. Pat. 12,470, June 27, 1895.

THE invention consists in applying silicon nitride, alone or mixed with other substances that will not expel ammonia,

such as kainite, to the soil as manure. The silicon nitride slowly develops ammonia, under the influence of moisture and of carbonic acid, thus supplying plants with the necessary nitrogen.—E. S.

Spent Molasses (Strontia and Lime Processes), Electrolysis of, Influence on the Composition of the Ash. Zeits. f. Elektrochem. 1896, 573—577.

THE author investigates the question as to whether a substantial improvement (as regards elimination of chlorine) in the quality of the crude potash—obtained as a by-product in sugar manufactories by the incineration of spent molasses—may be effected by the electrolysis of such molasses prior to incineration. Experiments were made on a small scale only (2—3 litres of liquid—currents of 10—100 watts). The best results as regards current efficiency and increase in the proportion of potassium carbonate were obtained by operating on highly concentrated liquids, and without the use of a porous septum between the electrodes. For example:—specific gravity of spent molasses, 44° B.; composition of ash before electrolysis, K_2CO_3 , 53.44 per cent.; Na_2CO_3 , 20.89 per cent.; KCl , 13.98 per cent.; K_2SO_4 , 7.77 per cent.; loss, &c., 3.92 per cent.; after electrolysis, K_2CO_3 , 61.44 per cent.; Na_2CO_3 , 18.42 per cent.; KCl , 5.74 per cent.; K_2SO_4 , 5.89 per cent.; loss, &c., 5.51 per cent.

With weaker liquids, the results were less satisfactory, probably because a portion of the current goes to waste in decomposing water. In any case the anode (carbon) is strongly attacked by the chlorine set free; whilst a non-conducting layer of lime and strontia—which must be frequently scraped off—is deposited on the cathode. From a monetary point of view, the improvement effected appears to be balanced by the cost of the power consumed, electrodes, &c. On the other hand the process would offer decided advantages if—and this point requires further investigation—the chlorine liberated by the current were found suitable for the production of bleaching powder.—H. T. P.

Water, Fermentative Changes in. W. E. Adeney. Trans. Royal Dublin Soc. V., Part II.

THE author describes the method and special apparatus which he has used, for studying quantitatively the changes in composition of the dissolved gases in liquids, which may accompany fermentative changes in the same.

He draws the following conclusions, among others, from his experiments recorded in this paper:—

That it is possible to demonstrate that the fermentation of substances under aerobic conditions, and in the presence of organisms usually present in water, takes place progressively in two distinct stages: (1) That in which the organic substances are completely broken down, the carbon and nitrogen being largely converted into carbonic anhydride and ammonia, a little organic matter remaining as such, but in an altered form; and (2) that in which ammonia is oxidised to nitrous or nitric acids, or both.

That the first stage of fermentation must be complete before the second stage can set in.

That the organic substances which result as products of the first stage of fermentation may undergo further change during the subsequent stage, and give rise to the formation of carbonic anhydride, and possibly also to nitric acid.

That peaty matters when present alone in a water, undergo very slow change, but when present with ammonia compounds in water they readily undergo fermentation, together with the ammonium compounds, just as the organic matters, which, as above stated, are formed during the first stage of fermentation of animal, vegetable, or artificial organic substances do, during the after-fermentation of ammonium compounds, which may have been also formed thereby, or which may have been previously present or added.

That the above-mentioned fermented organic matters, and also peaty matters, appear to determine the nitric fermentation of ammonia, since in their complete absence, similar organisms being present, only nitrous acid is obtained.

That during the intermediate stages of a fermentation of mixed peaty matters and ammonium compounds, various interchanges between the two appear to take place, the character and extent of which apparently depend on the relative quantities of peaty matters, ammonia, and dissolved oxygen present, and also on the character of the peaty matters themselves whether they have been freshly formed, or have undergone any previous fermentative changes.

That in the presence of small quantities of peaty, or other fermented organic matters, carbonic anhydride and ammonia may become "fixed" during fermentation, in appreciable quantities, no doubt, from Winogradsky's researches, to form organic matter.

That the formation of 1 part by weight of nitrous nitrogen during the fermentation of ammonia, in the complete absence of organic matter, is attended by the consumption of about 4.2 parts by weight of oxygen.

That for similar volumes of oxygen consumed, the quantity of nitrogen oxidised during the fermentation of ammonia is distinctly greater in the presence of peaty or other fermented organic matter than in their absence.

That for similar volumes of atmospheric oxygen consumed, the quantities of carbonic anhydride and of ammonia "fixed" are also more appreciable in the presence of those organic matters than in their absence.

That the observed facts in reference to nitrification may be summarised as follows:—

(a.) The nitrous organisms of soil thrive in inorganic solutions containing ammonia.

(b.) The nitric organisms of soil are gradually killed, or lose their vitality, in organic solutions containing ammonia.

(c.) The nitric organisms of soil thrive in inorganic solutions containing nitrites.

(d.) The nitrous organisms cannot oxidise nitrites to nitrates in inorganic solutions.

(e.) The presence of peaty or humus matters appears to preserve the vitality of nitric organisms during the fermentation of ammonia, and establishes conditions whereby it is possible for the nitric organisms to thrive simultaneously in the same solution with the nitrous organisms.

That by determining the changes in the composition of the dissolved gases, and that of the organic and inorganic nitrogen compounds, which accompany fermentation in natural and polluted waters, it is possible not only to differentiate easily fermentable from difficultly fermentable substances present in them, but to approximately estimate their quantity.

That such determinations are of very great value in the case of polluted waters, because, in addition to affording very accurate estimations of the total quantities of fermentable matters in them, in terms of the exact volume of atmospheric oxygen necessary for their complete fermentation, it is possible by proper examination to determine what fraction of such volume is required for the first stage of fermentation, and what fraction for the second, distinctions of the utmost importance in considering the technical aspect of the question of the pollution of rivers.

Brewing Waters, Nitrates in. R. E. Evans. J. Fed. Inst. Brewing, 1896, 2, 188—198.

WHEN the amount of nitric acid present in brewing waters exceeds 2 grains per gallon, deeper colour, sluggish

fermentations, and peculiar flavours are generally noticed; phenomena, though much modified by the character of the yeast, which are probably due to the bacteria being unaffected, whilst the development of the yeast is checked. The influence of nitrates is slight if a strong and healthy yeast be employed, whilst the same water with a weak yeast would give unsatisfactory results. The objectionable colour produced in worts brewed with water rich in nitrates is frequently attributed to the oxidation of the sugar or albuminoids; the author does not hold this view, for he found that a wort prepared with water containing 10 grains of potassium nitrate per gallon when boiled for four hours showed no increased coloration. Experiments were carried out with the object of studying the effect of nitrates in the brewing process. Wort containing 20 grains per gallon of potassium nitrate was fermented with ordinary yeast. No nitrates were found, thus showing that yeast cannot reduce nitrates to nitrites. A negative result followed an experiment to demonstrate whether yeast is similar to the higher plants in its capability of assimilating nitrates.

Steep Water, The Employment of Lime in. Wochenschr. f. Brau. 1896, 13, 401.

THE use of lime in steep water not only keeps the water fresh but causes the barley on the growing floor to retain a fresh aroma, whilst its vitality is increased and the growth rendered even. It is possible that the presence of weak alkali diminishes the solubility of phosphoric acid salts, and, moreover, renders the barley more permeable to water, thus favouring the absorption of the latter. Faulkner (Brewers J. 1895, 658) states that the employment of lime in steep water is becoming more general and is employed in one of the largest American maltings. The precipitate of chalk which forms in the tank carries down and retains water-borne bacteria, which play so important a part in the production of unpleasant smelling compounds when grown in a liquid rich in nitrogen. Phosphates are also well known to be especially favourable to bacterial development, and by diminishing their solubility the lime acts indirectly as an anti-septic. The author accordingly recommends the use of lime in steep water, and the use of calcium chloride in the mashing water.—T. A. G.

Fermenting Plant, The Cleansing of. B. W. Valentin. J. Fed. Inst. Brewing, 1896, 2, 184—185.

TO avoid difficulty in removing slumage incrustation deposited by yeast heads the author recommends painting with a wash consisting of whitening and water for two or three feet above the level of the beer, and allowing the layer to dry before the vessel is filled. After the fermentation is completed the yeasty slumage, together with the chalk, can be easily removed by a jet of water and a limited amount of brushing. The chalk prevents the slumage from persistently adhering to the wood; when once dry it is not acted on by the yeast heads, and, being practically insoluble in water or wort, it is not washed off to any appreciable extent, even when the wort is splashed up during reusing.—J. L. B.

Yeast Cells, Experimental Studies on the Variation of. E. C. Hansen. Annals of Botany, 1895, 9, 549—560.

IN 1870 Rees published a work on alcoholic fermentation fungi, in which yeast cells are referred by him to a particular genus *Saccharomyces*. He described a number of species, founding his views on the form and size of the cells. In 1883 and in subsequent years the author proved that the limits previously drawn were non-existent, and that from each of the species named by Rees it was possible to develop the rest. It is not in the form and size *per se* in which the distinguishing characters lie, but in the form and size depending upon particular conditions of cultivation. It is probable that the oval is the primitive form of yeast cell, so that the species *S. Pastorianus* has developed from the groups *S. cerevisia* and *S. ellipsoideus*.

The author has investigated the disappearance and recovery of spore formation, and has found that it is possible to bring about profound transformations of a permanent character. Thus, five species described in 1883, also several

beer bottom-fermentation and distillers' top-fermentation yeasts lost their power of forming spores when cultivated for a long period in an aerated wort at a temperature above the maximum for spore formation, and approaching that required for vegetative development.

Saccharomyces, which had lost the property of sporulation when placed in the earth, showed a decreased vitality as compared with their original forms. But in sugar solutions in which they had produced aleoholic fermentation they remained alive for several years, and the author considers that in this respect they do not differ much from the parent form.

A variation of *S. cerevisia* 1 can be effected by cultivating some of its spores partly in wort, and partly on the surface of yeast water-gelatin; the cultures being renewed fairly frequently during some months. It was found that the growth cultivated on gelatin gave 3 per cent. more alcohol than the corresponding cultivation in wort. The following experiment is cited to show the effect of the chemical composition of the nutrient liquid:—*S. Pastorianus* 1, one of the di-ease yeasts of beer, according to Mach and Portelli, affords a good wine. When this species is cultivated for a number of generations in a solution of cane-sugar in yeast water a growth is obtained, the cells of which have for a time lost the disagreeable properties which this organism formerly produced in beer. From this it may be seen that it is possible to act upon yeast cells in such a manner that they may be made to impart to fermenting liquids a taste and odour different from that originally characteristic of the yeast. The degeneration of culture yeast has been generally ascribed as the cause of most of the difficulties in brewery fermentations; this, however, is not in accordance with the author's views, for in no case has it been possible to carry one single species of *Saccharomyces* back to its progenitor.

Concerning the causes to which variation is due, the author is of opinion that special chemical compounds do not play any part, whilst the nutritive substratum and aeration are of importance only in so far as they permit of vigorous multiplication of the cells. The question of temperature is of most weight, for if it be too low the effect will not be sufficiently marked, whilst if too high the multiplication of the cells prematurely ceases; the consequence being that the inceptive change does not become permanent.—J. L. B.

Slaked Lime as a Disinfectant in Breweries. L. Steuber. Zeits. für das ges. Brauw. 1896, 44.

SLAKED lime has been used for a considerable time as a disinfectant for walls, &c. in breweries. Steuber has in consequence carefully investigated the action of quick-lime on yeast, and finds that protracted contact results in the destruction of the yeast. A thick coating of lime-wash on a wall, slightly contaminated with yeast, was effectual in disinfecting it. If, however, a layer of yeast of an appreciable thickness occur on the wall, mechanical cleansing must be resorted to before the application of the lime-wash. Better results were obtained where the wall dried slowly, the coating of lime-wash remaining moist for some time. The lime should be used as fresh as possible and have been exposed as little as possible to the carbon dioxide of the air. Lime wash has also the advantage of being inexpensive and easy of application, whilst the author's results prove its efficiency.—J. G. W.

Cellulose, Solution of by Enzymes (Cytase). J. Grüss. Wochenschr. Brau. 1895, 12, 1257—1259.

THE author has investigated the fact that malt extract can render certain forms of cellulose soluble. He finds that the hemi-celluloses which are readily hydrolysed by dilute acids, are also hydrolysed by the enzymes of malt extract; but their resistance to the action of enzymes varies. The enzyme attacks the hemi-cellulose through the cell walls, there transforming them, with the result that they become hyaline. In fact, as compared with hydrolysed cell walls, they behave differently towards dyes. Thus the hemi-cellulose of the date reed, when treated with potash and then alizarin, is stained violet, whereas when it has been previously subjected to the action of the enzyme, it assumes a much

fainter tint. Fuchsin or Congo red stains the intact cell-walls in the endosperm of barley and maize an intense red, but after treatment with the enzyme they remain uncoloured. The cell walls of barley are not dissolved but are converted into dextrinous substances (saccharo-colloids) insoluble in water. As stated by Brown and Morris the cytohydrolytic function of malt extract is destroyed by heating for a long time at 60°; the author also finds that the saccharifying action of such heated malt extract on starch paste is reduced by about one-tenth.

This behaviour does not necessarily involve the assumption of the presence of two enzymes, but may be due to the diastase becoming weaker in its action after heating.—J. L. B.

Raffinose, Hydrolysis of, by Soluble Ferments.

E. Bourquelot. *J. Pharm. et Chim.*, 1896 [6], 3, 390–394. THE author has investigated the action of the aqueous extract from a pure culture of *aspergillus niger* upon solutions of pure raffinose. He found that the specific rotatory power sank from $[\alpha]_D^{20} 103.12^\circ$ to $[\alpha]_D^{20} 50$ and 1 grm. of crystalline or 0.848 grm. anhydrous raffinose gave rise to 0.69 grm. of reducing sugar calculated as dextrose. According to Scheibler and Mittelmeier there are two stages in the hydrolysis of raffinose—

The first stage in the hydrolysis would require a specific rotation of $[\alpha]_D^{20} 52$ to 53 ; the author's experiments, however, show that the enzymes of *aspergillus niger* will carry the hydrolysis further than weak acids. The enzymes in an aqueous extract of baker's yeast had the same effect on raffinose as *aspergillus niger*, whilst extracts of bottom fermentation yeasts hydrolysed more strongly, since the specific rotation sank to 45° and the reduction corresponded with the formation of 0.79 grm. of dextrose.—J. L. B.

Attenuation, Some Remarks on. H. T. Brown

Brew. Trade Review, 1896, 10, 42–43.

THE application of cold air in attenuation can be effected by two methods. In the first, brine pipes are enclosed within the hood of the fermenting vessel, and are suspended near the surface of the wort. In the second, the air of the fermenting room is cooled down to 50–52° F. by brine pipes running the whole length of the room. The temperature of a union room in summer may be controlled in this manner without internal attenuators; but, in a fermenting room with large gyle-tuns, the water-coil attenuators must also be used. This method has disadvantages, for the cold air becomes saturated with moisture, which condenses on the walls, floor, and brine pipes, and the latter being always coated with ice, a considerable amount of drip is formed. Inasmuch as these brine pipes are often placed immediately over the gyle-tun, in the event of the drip troughs not being water-tight, the worts become contaminated. The continually moist surfaces of such a room form favourable media for the growth of moulds and other organisms, and this is the case with the surfaces of the fermenting vessels. The one essential in effectively cooling fermenting rooms, is, that the air should be fairly dry and its temperature some degrees above the dew point.—J. L. B.

Fermentation, The By-Products of. K. Kruis and B. Rayman.

Woch. für Brau. 13, 161 and 162.

THE authors have been endeavouring to ascertain whether the by-products of alcoholic fermentation, such as the higher alcohols, acetaldehyde, acetic acid, and the higher fatty acids, result from the action of the pure yeasts employed or whether they are the products of foreign organisms. In the course of their experiments they have arrived at the following conclusions:—Formic acid is slowly formed in wort kept for some time under sterile conditions with access of air and is therefore attributed to the action of oxygen on the constituents of the wort. Experiments of varying duration, with pure cultures of several distillery yeasts, under various conditions of temperature, showed that the by-pro-

ducts varied with the yeast, thus:—*S. cerevisia*, L., yielded formic acid, acetaldehyde, furfural, acetic acid, higher fatty acids, and amylie alcohol; *S. cerevisia*, V., gave traces of furfural and acetaldehyde but no amylie alcohol; *S. cerevisia*, Jørgensen No. 55, produced volatile acids and higher fatty acids together with slight amounts of acetaldehyde and fusel oil; *S. mycoderma*, D., gave formic acid, acetic acid, furfural, very little acetaldehyde, and no amylie alcohol; while *S. mycoderma*, B., yielded only formic acid, a good deal of acetaldehyde but no amyl alcohol.

Amylie alcohol, acetaldehyde, and furfural are therefore produced by pure cultures of yeasts without the aid of bacteria. A high fermentation temperature and anaerobic conditions favour the production of amylie alcohol. The authors do not consider it by any means certain that the production of fusel oil in industrial fermentations is entirely due to yeasts. They attribute the formation of valericianic acid and other higher volatile fatty acids to the decomposition of the nitrogenous constituents of the wort by the yeast employed.—J. G. W.

Beer, Fining of, by Light. Otto Reinke. Wochenschr. f. Brau. 1896, 13, 100.

IF a column of fermenting wort be illuminated by direct, or diffused sunlight, a rapid "fining" action takes place, the yeast being deposited in a compact state. Fermenting wort, which is not so illuminated or only feebly so, fines much more slowly and deposits its yeast in a more bulky and less compact layer. Since other sources of light behave in a similar manner, we have a means of rapidly clearing fermenting liquids. If, for example, the beer in the storage cask is illuminated, one obtains a somewhat rapid deposition of yeast together with resinous, albuminous, and glutinous bodies. Moreover, if electric lamps be suspended in fermenting vessels, quicker and better clarification of the beer is obtained. This influence of light can be readily demonstrated by placing a flask or cylinder containing a fermenting liquid before a window preferably one which faces south. Considerable experience has convinced the author that this fining action is not due to changes of temperature, but to the action of light alone.—T. A. G.

Lupulin, The Chemical Constituents of. H. Seyffert and R. von Antropoff. Zeits. ges. Brauw., 1896, 1.

BUNGENER'S hop-bitter acid is identical with the authors' β -hop-bitter acid, which was obtained from the petroleum spirit and ethylie ether extracts of hops, after precipitating the α -bodies with lead acetate, and which crystallised in fine needles and had a melting point of 83 – 86° C. It readily changed into β -resin when exposed to the air. The α and β acids when treated in ethereal solution with caustic potash, show slight formation of resin but no decomposition. Lerner's bitter-acid cannot possibly be identical with their α -acid. Beside the two hop-bitter acids, α and β , no other crystallisable body could be obtained, to which the name of hop-bitter acid could be applied. The γ -resin, a yellow, crystallisable body, has clearly the characters of a weak acid and evidently belongs to a quite different class of bodies. The hop resins are a mixture of substances in a continual state of decomposition and among the products of this decomposition are the resin-modifications investigated by Hayduck. To determine quantitatively the α and β bodies, the hops are exhausted with ethyl ether, and the residue from the distillation of this extract, treated with petroleum ether.—J. G. W.

Fermentation of Worts which have been rendered Antiseptic. An Improved Process for the. W. P. Thompson. Liverpool. From J. Effront, Brussels. Eng. Pat. 8123, April 24, 1895.

THE process described depends upon the elimination or suppression of foreign organisms by means of antiseptics, but under such conditions that the latter have no paralysing action on the fermentative power of the yeast, the method being intended more particularly for distillery purposes where it is important to obtain a high percentage of alcohol. The yeast is first acclimatised to the antiseptic which it is intended to add to the distiller's wort, and this is done by causing it to ferment successively several quantities of wort to which gradually increasing quantities of the antiseptic, e.g., hydrofluoric acid, formic aldehyde, salicylic acid, &c. have been added, and this process must be carried on until the yeast is able to endure at least double the amount of antiseptic added to the distiller's wort. The acclimatised yeast thus obtained is pressed, moulded into cakes, and these are then dried in vacuo at a temperature of about 35°. In five or six days the yeast will have formed spores and the temperature is then raised to 45° at which it is maintained for another five to six days. This dried yeast retains the high fermenting power of the acclimatised yeast. For its employment, 100 grms. are mixed with 10 litres of malt and maize wort containing the antiseptic, and the mixture maintained at 30°. As soon as fermentation has commenced, 40 litres of similar but fresh wort is added, and again after 24 hours four times its bulk (200 litres) is again added, the whole being then left to ferment. The product is then employed in the proportion of 2 hectolitres to 100 hectolitres of wort. The acclimatised yeast may also be used advantageously for the fermentation of molasses, as it requires the addition of only $\frac{1}{4}$ to $\frac{1}{2}$ per cent. of grain, and in certain cases the latter may be omitted altogether.—A. K. M.

Pneumatic Malting, Improvements relating to, and Machinery or Apparatus therefor. W. Adlam, Bristol. Eng. Pat. 10,096, May 22, 1895.

THE air employed for the aëration of the grain is conducted through a multitubular attenuating appliance, by means of which its temperature can be regulated, cold water, hot water, steam, or other suitable cooling or heating agents, being passed through an outer casing for this purpose. After issuing from the multitubular appliance, the air is conducted through a pipe fitted with a damper for its regulation, into a chamber into which a water-spray is discharged under pressure. Arrangements are described for regulating the fineness of the spray and also its temperature. After passing through the spray-chamber, the attenuated and saturated air is conducted by a pipe fitted with a hygrometer to the malting vessel.—A. K. M.

Fish Liver, An Improved Process for the Preservation of. C. M. U. Dable, Stanisund, Lofoten, Norway. Eng. Pat. 22,886, Nov. 29, 1895.

IN the process known as "boiling" fish liver in oil, the latter is, as a rule, merely heated to a temperature slightly above the boiling point of water, the object being to remove any water present and to preserve the liver. This is better

done by actually boiling the oil under a diminished pressure, equal to 12 inches of mercury. It is important that the temperature employed under these conditions be insufficient to burst or destroy the tissues of the liver, as otherwise the oil contained in the latter would mix with the oil in which the liver is preserved.—A. K. M.

Meat, Improvements in the Preservation of. C. L. Villar, Buenos Aires. Eng. Pat. 6920, March 30, 1896.

IN the process described (injection of solution of salt into the veins, emptied of blood), practically the whole carcass is preserved, and it is claimed that the meat appears as fresh and juicy as when first killed, whilst the hide has an increased value, and the wool and hair may be readily removed as soon as the animal is prepared. The leather produced from such hide is said to be thicker and better than that obtained in the ordinary way, since the tanning process may be completely and speedily effected.—A. K. M.

(B).—SANITATION; WATER PURIFICATION.

India-Rubber Tubing, Action of Coal-Gas upon. K. Grosheintz. Bull. Soc. Ind. de Mulhouse, 1896, 73.

COAL-gas, in passing through india-rubber tubing, undergoes absorption and diffusion, the former prevailing. In experimenting with tubing of different qualities it was found that this action is the more pronounced the smaller the proportion of mineral matter contained in the india-rubber. From these observations it follows that for gas-tubing employed in inhabited rooms, qualities containing a considerable amount of mineral matter are preferable to the more expensive black rubber tubing.—C. O. W.

PATENTS.

Smoke, Purification of; and the Recovery of Soot from the Products of Furnaces, Improvements in or relating to the. G. Mugna, Budrio, Italy. Eng. Pat. 5834, March 20, 1895.

THIS invention relates to the purification of smoke from furnaces, particularly that from locomotive boilers. The smoke is withdrawn from the chimney by a fan, and passed through a closed tank. The latter is partially filled with water, and is fitted with revolving vanes inside, which suck the smoke into the water. The soot is thereby washed out of it, and the purified product then passes into the atmosphere.—R. B. P.

Smoke Purification, An Improved System of. G. C. Marks, London. From M. Ringelmann, Paris. Eng. Pat. 9302, May 10, 1895.

THIS is a method of purifying the smoke from houses, factories, &c. of a town by a plant situated at a central station.

The smoke from the various parts of the town, instead of passing into open chimneys, is drawn into a network of conduits by means of a fan situated at the central station, where it is purified by being passed through suitable soot-settling chambers.—R. B. P.

Smoke [Purification], An Improved Method of and Apparatus for the Treatment of. D. W. Stone, Leamington Spa, and B. Chaplin, Rugby. Eng. Pat. 9739, May 16, 1895.

BY means of suitable fans, the smoke is first passed through a stove-chamber and then through a condenser fed with steam-jets.—R. B. P.

Sewage, Improvements in Apparatus for the Disinfection of. P. O'Dowd, Ballyglass, Mayo, Ireland. Eng. Pat. 8877, May 4, 1895.

An intercepting tank or chamber is provided, in connection with the house drains, fitted with screens, and containing chemical reagents, such as copperas and peat charcoal. The house sewage filters through these materials, and the accumulated deposit is removed from time to time and used for manure.—L. A.

Sewage, Improvements in the Treatment of, and in Apparatus therefor. D. Cameron and F. J. Commis, Exeter. Eng. Pat. 21,142, Nov. 8, 1895.

CRUDE sewage is caused to flow through a closed tank (air-tight cover), in which it undergoes purification by bacteriological action. The inlet and outlet are arranged so that the flow of sewage does not disturb the brown scum which begins to form upon the surface of the sewage when the tank has been in operation for two or three days. This scum is formed by bacteriological action; and the further changes which take place in the tank lead to the solution of the organic portion of the sludge and the production of an effluent which is so free from suspended matter as to be fit for treatment by coke-breeze filters or by irrigation.

—L. A.

(C).—DISINFECTANTS.

Insect Destroyers. E. Perroneito. Arch. ital. de Biolog., 23, 47.

THE author has investigated the action of various solutions on the vitality of the eggs of *Bombyx mori* with a view of ascertaining the best means of destroying insects prejudicial to agriculture. These eggs retained their vitality after several hours' immersion in solutions of ammonia (0.3 per cent.), milk of lime, sodium chloride, iron and copper sulphates, potassium permanganate (1 per cent.), potassium cyanide (1 per cent.), mercuric chloride (0.1—0.2 per cent.), sulphuric, hydrochloric, and nitric acids (1—5 per cent.), phenol and thymol, carbon bisulphide (5 per cent.), benzene or oil of turpentine and emulsions of kerosene or of olive or sesame oils. All mineral oils exert a deadly action on the eggs, but the intensity of the action varies considerably. The larvae of the Diptera resist the action of mineral oils and their emulsions; they are, however, killed by carbon bisulphide. In lime water is found a sure and cheap means of destroying earthworms.—J. G. W.

PATENT.

Sewage and the like, An Improved Means for Treating. J. J. Hood and A. G. Salamon, London. Eng. Pat. 11,527, June 13, 1895.

WELDON mud is treated so as to remove from it the calcium chloride; it is then air-dried until it assumes the form of a fine powder, which, probably owing to its finely divided state and powerfully oxidising properties, is found to possess in a remarkable degree the property of deodorising faecal matter when sprinkled over it. In this form the substance is used for dry closets and the like. The washed mud may also be used in a wet state if desired, and may be thus applied to the treatment of all forms of sewage.—L. A.

XIX.—PAPER, PASTEBOARD, Etc.

Sulphur, Formation of, in the Sulphite Process of Treating Wood. A. Franke. Papier Zeit. 1896, 21, 599.

FREE sulphur is formed in the process of digestion of wood with bisulphite as carried out in the Salomon-Brünger digesters. In this process also an incrustation is formed on the sides of the digester, composed of CaSO_3 (63.23 per cent.), CaSO_4 (26.77 per cent.), and organic matter (9.93 per cent.).

At the high temperature prevailing in these digesters (152 °C.), the oxy-sulphur compounds react with the organic matter of the deposit, sulphides being formed, which react in the well-known way with any fresh sulphurous acid.

The author thus accounts for the appearance of the free sulphur.—C. F. C.

Sulphite Pulp, Washing and Bleaching of. Prakt. Handbuch der Papierfabr. [41], 1896, 1591.

SULPHITE pulp is generally bleached like the pulp from rags and other raw materials, as described on pages 1412-13 of this book.

It is necessary to thoroughly wash the pulp before adding the solution of bleaching powder, to eliminate all foreign matters, including sulphur salts, as completely as possible.

W. Palmar reports in Papier Zeit. No. 70, 1890, the results of experiments carried out at the University laboratory of Upsala, to ascertain the cause of the reddish colour often formed after exposure for a time to the air. The pulp, after the lye was run off, was washed in a beating engine, and samples of the washing water and the pulp were taken after $\frac{1}{2}$, 1, 1 $\frac{1}{2}$, and 2 hours' washing. The water contained at first 0.0404, after $\frac{1}{2}$ hour 0.0187, and after 1 hour 0.0106 grm. of SO_2 per 100 c.c., and on continued washing only a little acid was found, so that more washing would be useless. Fresh sulphite pulp contained 1.45 per cent. of ash, of which 1.2 per cent. was CaSO_3 . The latter being only slightly soluble in water, it is difficult to remove it by washing, and it is better to allow the CaSO_3 to settle in large sand-catchers.

When a solution of bleaching powder is added in the bleaching engine, the sulphite pulp often turns to a reddish or brown-reddish colour, but loses the colour when more bleaching powder is added. This colour does not arise from the encrusting materials not removed by boiling, as mechanical pulp containing the whole of the encrusting matter does not show this colour. The fact that unbleached sulphite pulp get rose or violet tinted in air rich in ozone, and especially in rooms where the air contains chlorine, shows that an oxidation of some until now unknown matter contained in the pulp takes place.

According to the experiments of Dr. A. Frank, the rose colour is formed principally by the oxidation of the SO_2 , forming SO_3 , this latter carbonising the encrusting matter by the abstraction of water. This reddening is seen in a stronger manner in the carbonisation of textile fabrics. To prevent the formation of the colour when sulphite pulp is mixed with other pulps, care should be taken that no free chlorine is present, and this may be prevented by adding some antichlor or sulphite lye.

To see whether oxidation was the cause of the colour, Ferd. Wolesky treated different pulps with the oxidising agents in the following table, and obtained the results given:—

Name of Reagent.	Sulphite Pulp (Mitscherlich).		Sulphite Pulp (Ritter-Kellner).		Soda Pulp.	Pulp.
	Ia.	IIa.	Ia.	IIa.		
Solution of bleaching powder	Rose	Rose	Rose	Rose	Light pink	Yellow
Potassium ferricyanide	Rose	Rose	Rose	Rose	Light pink	..
Ferric chloride	Violet-red	Violet-red	Violet-red	Violet-red	Light violet	Green
Mercuric chloride	Rose	Rose	Rose	Rose	Light pink,	..
Potassium bichromate	Rose	Rose	Rose	Rose	but very	..
Potassium permanganate	Rose	Rose	Rose	Rose	indistinct	..

The solutions of ferric chloride, potassium bichromate, and potassium permanganate were used very weak, and that of mercuric chloride rather stronger. The pulp was soaked in the solutions.

When bleaching pulp, the red colour is disregarded, but more bleach is added and the mixture heated to 30° to 40° C., and sulphuric acid is then added until the colour disappears. The solution of bleaching powder seems to change the colouring matters to colourless ones, but it is not known what the change is, neither is the nature of the colouring matter known. The fact that from 14 to 22 per cent. of bleaching powder is required, indicates that it has to perform other actions besides bleaching. The amount of bleaching powder required increases with the amount of encrusting matter left in the pulp. These encrusting matters have to be decomposed before the bleach can get to the fibres, therefore it is much better to beat up the pulp beforehand in such a manner that no bundles of fibres remain, and to wash thoroughly. Some makers wash the pulp with a hot solution of caustic soda, which decomposes many substances unaffected by the SO_2 . Other makers put the pulp into a 13 per cent. solution of bleaching powder, warm, and add 2½ per cent. of sulphuric acid, after an hour's time. The pulp, which is frequently orange-coloured, is washed for 2½ hours, until it looks blue-grey, and it is then rebleached by a solution of 1½ to 2 per cent. bleaching powder for 1 hour, and at the last a solution of ½ per cent. sulphuric acid is added.—S. P. E.

Resin in Sulphite Wood Pulp. H. Mayr. Prakt. Handbuch der Papierfabr. [4], 1896, 1592–1596.

The following table gives the amount of resin per cubic metre of absolutely dry wood from the branchless trunks of coniferous trees:—

Name of Tree.	1 cm. weighs	1 cm. contains Solid Resin.
	Kilos.	Kilos.
Pitch pine (N. America)	700	61.1
Weymouth spruce (N. America) ..	386	21.5
Old spruce (Bavaria)	463	19.6
Larch (Hamburg)	463	18.8
Red spruce (Hamburg)	506	18.7
Old larch (Bavaria)	539	17.2
Weymouth spruce (Bavaria)	343	16.7
Red spruce (Norway)	402	9.9
Douglas fir (N. America)	476	9.2
Fir (Hamburg)	423	8.2
Pine (Hamburg)	412	6.6
Pine (Norway)	400	3.5
Fir (Bavaria)	373	3.1

In the soda treatment, the different resins get converted into soluble soaps, and are easily washed out, but the treatment with sulphite lye has not this effect. Only the soluble parts of the resins go over with the lye. Care should be taken to wash out the dissolved resin adhering with the lye to the fibre before it hardens again, as oxidation of the resin occurs as soon as it comes in contact with the air.

The worst forms of resins are those which are insoluble in hot sulphite lye, and which therefore stay in the pulp, causing brown and yellowish spots to appear in the paper. By grinding such pulp, the resin settles on the sides and other parts of the grinders and kollergangs in dark, sticky masses. It also seems as if a part of the resin formed an insoluble resin-lime soap, with the lime from the lye or the water, since as much as 12 per cent. of lime salts are sometimes found in the accumulations of resin.

Experience has shown the best way to obtain wood pulp containing least resin. The wood cut down in winter contains the least resin, and becomes more free from resin the longer it is stored after being barked. In the spring time, when wood is in its most sappy state, all bark particles and dust coming in contact with the wood adhere so firmly that it is hardly possible to remove them. The drier the wood, the easier and cleaner it is to cut and bark. In any case the felled wood should be brought to the storehouse as soon as possible, and stored in such a manner that the air can have free access to it. To keep wood healthy, it

should be barked as soon as possible, although it will be found impossible to begin before the middle of March in most years, on account of the cold weather and the risk of the barked wood being damaged by freezing.

It seems doubtful whether wood contains the least resin in winter, but it is hard, and easy to remove during the cleaning and sorting. It is also likely to be retained by the strainers, whilst the soft, sticky resin passes through all the processes, later on hardening, and being then very difficult to remove on account of its fine state of distribution.

According to E. Partington, the tar-like particles develop only through the fibres being rubbed at the beaters after boiling. Neither in the wood nor in the boiled pulp are they said to be found. The tar-like particles settle, according to Partington, upon the fibres, as well as on the utensils and boxes, upon which they form black films, which are rubbed off by the circulating pulp, and soil it. By using paraffin oil of sp. gr. 0.8 to 0.85, and inflammable between 27° and 49° C., the formation of these tar-like particles can be prevented. An average addition of 7 to 9 kilos. of paraffin to 1,000 kilos. of dry pulp is sufficient. Pulp, when boiled a long time, requires less paraffin. The paraffin may be added at the pulp opener or disintegrator, but Partington prefers to add it to the pulp in the beating engines.

The tar-like particles, however, are probably not formed by rubbing, but by the oxidation and hardening of the resin in the beaters by contact with the air. The paraffin may simply act so as to keep the air from the pulp until the resin is washed out, by forming a thin skin or film over the watery pulp.

The particles of resin, being lighter than water, float on the surface, and many paper-makers use laths covered with strips of long-haired felt, which float on the thin pulp when passing over the sand troughs, and retain most of the resin.

In practice it was found that felt strips are frequently torn off, so they have been more recently replaced by thin strips of brass or other material, placed obliquely in the sand trap, and dipping a few centimetres into the pulp. The resin is stopped by these, and accumulates at one corner of the cross-strips, from whence it can be easily removed.—S. P. E.

Paper, A Fibrous Filling for. Chem. Trade J. 18, 368.

This is a new material for filling paper, which has been brought forward under the name of "Nematolith." It is a species of pure asbestos, but it is free from the iron, lime, and sulphur compounds that are usually found in crude mineral asbestos. The raw material from which nematolith is prepared was found on analysis to contain 96 per cent. of pure silicate of magnesia. Nematolith improves the white tone of the paper.

It is readily retained by the pulp, as on incinerating the paper when finished, as much as 95 per cent. of the material added is found. It is unattacked by alkalis or acids, even sulphurous acid. Even when it is used in large proportions, the paper does not lose in body or touch. The best method of using it is to boil 220 lb. of the filling with 220 galls. of water; a little starch may be added to more perfectly fix the filling. It is introduced after sizing.—A. S.

Aluminium Sulphate. Papier Zeit. 21, 1896, 599 and 794.

See under XXIII., page 473.

Paper Colouring (in the Engine). H. Spitteler. Papier Zeit. 21, 1896, 763.

See under VI., page 449.

PATENT.

Paper, Treatment of. R. Aitken, London. Eng. Pat. 2709, Feb. 7, 1895.

The object is to impregnate paper, either plain or printed, or water-colour drawings, with a waterproofing material such as paraffin, or with an antiseptic substance such as naphthalene, with or without a dye. This is accomplished by steeping the paper in a solution of the substance in a volatile solvent, and then removing the solvent by evaporation. Mural advertisements may be thus waterproofed and wall-papers made sanitary.—L. A.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Alcohols [of the Terpene Group], Method of Purifying. F. Tiemann and P. Krüger. Ber. 29, 1896, 901—903.

THE following method for the purification of alcohols is specially applicable to those of the terpene group, when it is often necessary to separate the alcohol from certain indifferent substances, chiefly hydrocarbons. It is known that terpene compounds are easily decomposed and consequently cannot resist prolonged heating at a high temperature, especially in contact with strong acids, as they are apt to undergo molecular rearrangement, eliminating water, and forming hydrocarbons. In contact with alkalis, however, the terpene alcohols are much more stable. These facts, together with this, that alcohols when heated with the anhydrides of dibasic acids (e.g., succinic, phthalic, and camphoric anhydrides) readily form ester acids, form the basis of the method recommended by the authors.

The alcohol, dissolved in ether if necessary, is first of all converted into the sodium alcoholate. To this substance suspended in absolute ether an equivalent quantity of succinic or phthalic anhydride is added, when, after standing for some days at the ordinary temperature, the sodium ethereal salt is formed according to the equation—

On now adding water and shaking, the sodium ethereal salt goes into solution, whilst the excess of phthalic anhydride, together with unchanged and regenerated alcohol, remains in the ether. By extracting the aqueous solution with ether, the sodium ethereal salt may be completely purified. In order to obtain the pure alcohol the sodium ethereal salt is saponified at the ordinary temperature with alcoholic potash. Camphoric anhydride ought not to be employed instead of phthalic anhydride, as the compounds so formed are in general very difficult to saponify. Acid ethereal camphorates, which can be saponified, can, however, be prepared by heating camphoric anhydride with the corresponding alcohol.

The advantage of this method depends on the fact that the alcohol may be purified without any rise in temperature, and without the use of strongly acid substances. The disadvantages consist in the difficulty of working the process quantitatively, and in the large dissociation of the sodium compounds. Only 40—60 per cent. of the alcohol can be obtained in the pure state.—J. S.

Iodoformine, Preparation of. E. Konteschweller. Pharm. Central-H. N.F. 1895, 16, 651 and 684.

THIS inodorous, and hence to many patients more acceptable, preparation of iodoform is obtained by bringing hexamethylenetetramine and iodoform together in the ratio of their molecular weights. Or alcoholic solution of hexamethylenetetramine is mixed with the corresponding quantity of iodoform dissolved in hot alcohol. The precipitate so obtained, after pressing and drying between filter-paper, is a white inodorous powder.

Another and simpler method of preparation is to rub 26 grms. of hexamethylenetetramine with 74 grms. of iodoform, after the addition of a little absolute alcohol, to dryness in a mortar.—J. S.

Di-iodomethyl Salicylate ("Sanoform"). Pharm Zeit. 12, 320.

A. ARNHEIM has found in this compound an efficient substitute for iodoform. It is prepared by the action of iodine upon methyl salicylate, and contains 62.7 per cent. of iodine. Its form is that of a white crystalline powder of melting point 110° C. It is soluble in 10 parts of hot alcohol, and also soluble in ether and in vaseline. Langaard states that this di-iodomethyl salicylate is not poisonous, and that it possesses other advantages over iodoform.

Pseudoaconitine. M. Freund and R. Niederhofheim. Ber. 29, 1896, 852—855.

STARTING with pseudoaconitine, $C_{35}H_{39}NO_{12}$, the authors have prepared and examined the hydriodide, aurochloride, nitrate, and thiocyanate. When ψ -aconitine is boiled with water it is converted into acetic acid and picro- ψ -aconitine, $C_{34}H_{47}NO_{11}$, which differs from ψ -aconitine inasmuch as it does not form a crystalline nitrate, and the aurochloride is easily soluble in cold alcohol. On further hydrolysis by boiling with freshly prepared caustic potash, picro- ψ -aconitine is converted into pseudacarine, $C_{25}H_{35}NO_8$, which forms a well-defined compound with acetone and veratric acid.

—J. S.

Orypiperidine Hydrochloride ("Eucaïne"), $C_{19}H_{27}NO_4 \cdot HCl$. Pharm. J. 1896, 342 and 413.

THIS is a new substitute for cocaine for producing local anaesthesia. It does not, it is stated, possess the property (a disadvantage in the case of cocaine) of affecting the action of the heart, and the anaesthesia lasts longer and is more widespread. An injection of 30 grains can be tolerated. Eucaïne is not decomposed on boiling its solution. The base itself is almost insoluble in water, but the hydrochloride is readily soluble.

Ethereal Oil of Ledum Palustre. J. Trapp. Pharm. Zeits. Russl. 1895, 34, 962.

THE author calls attention to the fact that the yield of ethereal oil obtained on the distillation of *Ledum palustre* depends on the period of vegetation of the plant, and that this fact explains the variations in the results obtained by other authors. The largest yield of an ethereal oil rich in ledum-camphor is obtained from the plant at the time of flowering.—J. S.

"Galactite" from the Seeds of the Yellow Lupin.

H. Ritthausen. Ber. 29, 1896, 896—899.

FROM an alcoholic extract of the seed of the yellow lupin the author has obtained a beautiful crystalline compound (1.05 per cent. of the seeds) for which he proposes the name "Galactite." The composition of the substance is represented by the empirical formula $C_9H_{15}O_7$, and it may possibly be related to Quercite. On hydrolysis by dilute sulphuric acid, it gives over 60 per cent. of galactose.

—J. S.

Convicine: Alloxantin obtained on the Hydrolysis of.

H. Ritthausen. Ber. 29, 1896, 894—896.

CONVICINE prepared from broad beans (*Vicia Faba minor*) and vetches (*Vicia Sativa*) gave on hydrolysis with sulphuric or hydrochloric acid 34—37 per cent. of a crystalline substance, which in the case of the first-named preparation is certainly, and in the second probably alloxantin. Further observations lead the author to suppose that Convicine, $C_{10}H_{15}N_3O_7 \cdot H_2O$, is a glucoside similar to vicine, on which latter further details are promised.—J. S.

Alloxantin, A Reaction of. H. Ritthausen. Ber. 29, 1896, 892.

See under XXIII., page 475.

Rhodinol, the Active Principle in Otto of Roses, Constitution of. Ph. Barbier and L. Bouveault. Comptes rend. 122, 673—675.

THE authors find that the rhodinol extracted from roses is identical with that obtained from the essence of pelargonium. Rhodinol is a primary alcohol, forming upon oxidation the aldehyde rhodinal. Rhodinic acid and the rhodinate of rhodinyl were also prepared. Rhodinic acid and rhodinyl acetate combine with two atoms of bromine. This fact proves the existence of an ethylene bond.

By further oxidation of rhodinol, acetone and β -methyl adipic acid were obtained. The formula deemed most probable is—

—V. C.

Mandelic Acid, New Process for the Manufacture of [for Antipyrine Salt]. C. Pape. *Chem. Zeit.* 1896, 20, 90.

SIX: the introduction of the antipyrine salt of mandelic acid the author has improved the method of manufacture. Commercial benzoic aldehyde is converted into the well-known bisulphite compound by shaking with a concentrated solution of sodium bisulphite. This compound is pressed, washed with alcohol, if necessary, and dried. It is then made into a thin paste with water and mixed with the theoretical quantity of a concentrated solution of potassium cyanide. The undissolved portion of the bisulphite compound goes rapidly into solution, and the nitrile of mandelic acid immediately separates out as an oil, which is removed from the aqueous liquid as quickly as possible. It is thus obtained very pure, and is therefore easily converted into mandelic acid. For this purpose the freshly prepared nitrile is mixed with three times its volume of concentrated hydrochloric acid, when the mixture becomes heated up to the boiling point, at which temperature it is kept for some time and the conversion into mandelic acid is complete. The separation and purification of the acid is conducted in the usual way.—J. S.

Levo-Fenchone, a New Isomer of Camphor. O. Wallach. *J. de Pharm. et de Chim.* 1896, 3, [9], 465.

WALLACH has discovered in the essential oil of Thuja a levo-fenchone exactly similar to the dextro-fenchone found by him in oil of fennel. The fraction of oil of Thuja boiling at 190°–200° contains levo-fenchone and thujone. This is warmed in portions of 20 grms. with 80 grms. of concentrated nitric acid; the unaltered fenchone is distilled over by steam, dried, and purified by crystallisation in a freezing mixture.

Levo-fenchone is exactly similar to dextro-fenchone, except in its rotatory power, $\alpha_D = -66.94^\circ$; sodium amalgam reduces it to fenchyl alcohol, the rotatory power of which ($+10.36^\circ$) is equal to that of fenchyl alcohol prepared from dextro-fenchone, but of opposite sign; in brief, a series of compounds has been prepared from levo- similar to those from dextro-fenchone.—A. C. W.

Menthone: Its Conversion into Thymol. E. Beckmann and H. Eickelberg. *Ber.* 1896, 29, 418.

IN chloroform solution, dextro- and levomenthone react with two molecules of bromine, forming a dextro-rotatory dibromomenthone, $C_{10}H_{16}Br_2O$, of melting point 79°–80°, which contains the carbonyl group unaltered, and regenerates menthone by reduction with zinc-dust and acetic acid. The dibromomenthone on boiling with quinoline is converted into thymol; thus menthone is 1-methyl-3-keto-4-isopropylhexamethylene.—A. C. W.

PATENTS.

Albumin-Tannin Compound [Astringent], Improvements in the Manufacture or Production of an. W. L. Wise. London. From Knoll and Co., Ludwigshafen, Germany. Eng. Pat. 6110, March 23, 1896.

ALBUMINATE of tannin, if employed in a freshly precipitated state, will be digested by an effective gastric juice within a few minutes; if it be air-dried, its digestion will occupy about two hours; but if it has been heated for 6 to 10 hours at 110° C. and upwards, it will hardly be attacked by gastric juice, even within 24 hours, and will, in consequence, be well fitted for producing an astringent action on the mucous membrane of the intestine without affecting that of the stomach, and in this way causing indigestion. The following method of manufacturing albuminate of tannin of the required degree of insolubility in gastric juice has been found to give satisfactory results. Ten kilos. of albumin and 20 kilos. of tannic acid are dissolved separately in cold distilled water, and the solutions are afterwards mixed whilst being continually stirred. The mixture having been allowed to settle, the supernatant solution is decanted, and the precipitate is repeatedly lixiviated to free it from excess of tannic acid; it is then filtered, pressed, and dried, and is finally heated during a

period of 6–10 hours at 110°–150° C. either in an air-bath or in some liquid, such as xylene, which is without action on the albuminate. The yield is about 10 kilos.—A. G. B.

A Pharmaceutical Substance [Active Constituent of Thyroid Gland], Improvements in the Manufacture of, and in the Purification of the same. H. E. Newton. London. From "The Farbenfabriken vormals F. Bayer and Co.," Elberfeld, Germany. Eng. Pat. 12,295, June 25, 1895.

FRESH thyroid glands (of sheep or other animals), freed from fat, are boiled with 4 parts of sulphuric acid of from 5–10 per cent. strength, for 20–30 hours with a reflux condenser. The precipitate formed on cooling contains almost the whole of the active constituent; the part remaining in the filtrate is obtained by neutralising or adding common salt, evaporating down, and cooling. The crude product is extracted with hot alcohol, and the alcoholic solution either evaporated down or precipitated by ether, and finally washed with ether or ligroin.

The active principle is neither an albumin nor a peptone; it has the properties of a weak acid and contains iodine; for medicinal purposes it should be mixed with some neutral substance, such as sugar of milk.—A. C. W.

Pyrocatechin-Monoacetic Acid [Medicament; Substitute for Guaiacol] Process for Obtaining. W. Majert, Falkenberg, Prussia. Eng. Pat. 17,160, Sept. 14, 1895.

CHLORACETIC acid and pyrocatechol in molecular proportions in aqueous solution are boiled with an inverted condenser, and sodium hydroxide or carbonate gradually added in calculated quantity. On cooling, sodium pyrocatecholmonoacetate separates, and is purified by recrystallisation. The acid $OH.C_6H_3(O.CH_2.CO_2H)$ forms whitish crystalline needles moderately soluble in water, melting at 131°, but by overheating is changed to its lactone, melting at 56°.—A. C. W.

Oxypiperidine Carbo-Acids and Derivatives therefrom, Production of. A. Zimmermann, London. From Chemische Fabrik auf Actien, vormals E. Schering, Berlin. Eng. Pat. 12,465, June 27, 1895.

THE production is claimed of γ -hydroxypiperidine carbonic acids having the general constitution—

as the carbonic acids derived from triacetoneamine and analogous derivatives from γ -piperidone, as benzalldiacetoneamine and vinylldiacetoneamine, by first linking hydrocyanic acid to a γ -piperidone derivative—

and then saponifying the nitrile produced to a γ -piperidine carbonic acid. Also producing benzoylated and tolylated alkyl esters from the said γ -hydroxypiperidine carbonic acids is claimed, and, moreover, the production of a variety of other esters. Thus it is proposed to form benzoyl- γ -hydroxypiperidine carbonic esters and *n*-alkyl benzoyl- γ -hydroxypiperidine carbonic esters, &c., by linking hydrocyanic acid to triacetoneamine, &c., saponifying the nitrile so produced to γ -hydroxypiperidine carbonic acid, and converting the latter into ester, and into compounds thereof, by replacing the H of the OH group with benzoyl, &c., and the H atom of the NH group by alcoholic radicals. Other variations are described, and the substances produced as described, are laid claim to.

XXI.—PHOTOGRAPHY.

Gelatin-Chloride Dry Plates, New Sensitisers for. Eder and Valenta. Dingler's Polyt. J. **300**, [1], 18.

THE authors investigated several substances belonging to the Rose Bengal class, and found that tetra-iodotetrachloro-fluorescein produced the best effect. The sensitising action of this substance reaches a maximum in the yellowish-green before the D line and extends to D $\frac{1}{4}$ C. Of the Rhodamines examined, the 3 B of the Badische Anilin und Sodafabrik proved to be good, with a maximum effect in the neighbourhood of E $\frac{3}{4}$ D and extending to D $\frac{1}{2}$ C. Still better are the actions of tetrachlorotetra-ethylrhodamine hydrochloride and tetrachlorotetra-ethylrhodamine ethyl ether, which reach as far as D $\frac{1}{2}$ C and D $\frac{2}{3}$ C. Nitrilo-rhodamine takes effect in the orange-red as far as D $\frac{1}{2}$ C. These colouring matters produce a greater sensitiveness in the blue than either Erythrosine or Rose Bengal. Good sensitisers for the region of the green are Acridine yellow and Acridine orange, of which the former is the better. Diamidodimethylacridine hydrochloride (A. Leonhardt) gave a closed spectrum extending from D $\frac{1}{2}$ E nearly to the violet, and is hence valuable for spectrum work and for three-colour printing.

Gelatin Coatings from Paper Supports in the Manufacture of Photographic Films, Improvements in Means for Facilitating the Separation of. J. B. B. Wellington. Elstree, Herts. Eng. Pat. 11,821, June 18, 1895.

PAPER is coated (1) with an alcoholic solution of sandarac, copal, &c., (2) with gelatin containing chrome alum, and (3) with celluloid. The backing is then stripped off, and the film coated with the sensitive emulsion. As an alternative process, the silver film may be applied direct to the gummed paper and the celluloid afterwards. The essential point consists in the use of the layer of resin to assist in the stripping.—F. H. L.

XXII.—EXPLOSIVES, MATCHES, Etc.

Nitroglycerin, On the Boiling Point of. L. de Bruyn. Rec. trav. Chim. des Pays-Bas, 1895, **14**, 131.

ACCORDING to Champion, the boiling point of nitroglycerin is about 185°. The author, however, found that on heating

nitroglycerin to 160° under a pressure of 15 mm., volatilisation, but no boiling, took place. Since the boiling point is reduced about 100° by lowering the pressure to 12–20 mm., the author concludes that the boiling point of nitroglycerin must at least be above 200°.

Champion gives the temperatures of explosion of nitroglycerin and gun-cotton as 257° and 220° respectively. These were also found to be inaccurate, as neither substance could be heated above 190° without exploding.—J. S.

PATENTS.

Smokeless Explosive or Gunpowder, A New or Improved. T. Hawkins, S. H. Hawkins, and H. Hawkins, Upton Park, Essex, and the Donmithorne Gun Patents and Ammunition Company, Limited, London. Eng. Pat. 6271 March 26, 1895.

THIRTY-TWO parts of chloride of potash, 16 parts of sugar, and 1–2 parts of wool-pulp flour or lampblack are mixed together, and then 1–4 parts of bichromate of potash incorporated, the last ingredient being dry or mixed with an equal quantity of water. The paste is granulated and dried by hot air or other methods. The explosive may be used for small arms, ordnance, charging shells, blasting, &c.; when intended for blasting, the wool-pulp flour or lampblack is omitted, and an increased amount of bichromate of potash employed.—A. Amorphous Phosphorus as Substitute for the Yellow Phosphorus for Matches, Primings, and the like, Process for rendering applicable. Abel and Imray, London. M. Bals and E. Gurovits, Vienna. Eng. Pat. 4714, March 2, 1896.

SULPHUR is melted and mixed with amorphous phosphorus, or sulphur and phosphorus are mixed and heated to the melting point of the former. On cooling, the compound can be pulverised without danger. For igniting masses, 100 parts of sulphur are mixed with 50–150 parts of phosphorus. The mixture burns slowly with an inextinguishable flame, and is adapted for signalling purposes; mixed with "chloride of potash" (chlorate?), glass, and other igniting and binding materials, it ignites by friction on any surface, without noise.—A. C. W.

XXIII.—ANALYTICAL CHEMISTRY.

APPARATUS, ETC.

Fractionating Column. G. W. A. Kahlbaum. Ber. **29**, 71–73.

THE apparatus described consists, as will be seen from the figure, of an outer tube which fits into the distilling flask and carries the thermometer. The latter is suspended inside a narrower tube which communicates at its lower end with the condenser. By this arrangement the thermometer is surrounded by a double envelope of vapour and the bulb is protected from splashes.

—T. A. L.

Mixing Apparatus for Accelerating Chemical Reactions.
V. Markovnikoff. *Annalen*, 1895, **269**, 254—257.

The apparatus consists of a cylinder of copper (2 mm. thick) *a* (Fig. 1) open at both ends. At each end a band

Fig. 1.

b (Fig. 1 and 2) is fixed outside, to which iron bands *c* (Figs. 1 and 2) are soldered. As the hermetic closing of the apparatus depends on these iron bands, they must be perfectly even, and sufficiently thick (4–5 mm.). The cylinder is closed, at both ends, by perfectly flat brass plates *d* (Fig. 1) about 3 mm. thick, which are screwed to the iron rings *c* by seven or eight iron rods *e* (Fig. 1), which are fixed at one end (at *h*) to the brass disc *d* employed as fly-wheel and pass through the holes *g* (Fig. 2) at the

Fig. 2.

Fig. 3.

other end. A layer of lead, or asbestos, is inserted between the iron rings and the brass plates. There is one opening, *J*, in the cylinder, which is closed by the screw *k*, or by a tap, for letting off pressure if required.

The cylinder is rotated by means of a handle fixed to the fly-wheel *f*, or it may be connected with a turbine or other motor. For varying the speed, when a motor is used, there are two wheels, *f* and *m*, of different diameter, to take the connecting cord.

For mixing liquids in the cylinder there are five lead or tin plates *o o* (Figs. 2 and 3) soldered to the inside of the vessel. They are nearly as long as the cylinder, and their width is three-quarters the radius of the cylinder. The plates are provided with openings *p*.

The inside of the apparatus is well tinned, but for some purposes a porcelain cylinder may be used. The advantages

of the apparatus are its lightness, and the fact that it can readily be heated by placing a burner underneath, or cooled by running water over it. A convenient sized apparatus is one which holds about 1½ litre. It should not be more than three-quarters full.—N. H. J. M.

PATENTS.

[Pyrometers], *Improvements in or connected with Appliances for Testing the Range of Heat in Furnaces, or Recording other such High Temperatures.* G. Watson, C. W. James, R. L. Bullock, all of Leeds. Eng. Pat. 3379, Jan. 16, 1895.

THE system used is that of suspending a number of discs of materials having different melting points. The latter are previously determined and marked upon the discs. The principle followed is that of exposing to the heat to be measured, a successively graduated and temperature-stamped series of test-pieces of metal or alloy, systematically arranged to melt in their successive order up to the point reached by the temperature in question. On melting, the pieces fall off a wire, till at length a point is reached at which a particular test-piece refuses to melt. Various arrangements are described and illustrated.—R. B. P.

Gases, Specific Gravity of; Apparatus for Ascertaining. A. Custodis, Düsseldorf, Germany. Eng. Pat. 7791, April 18, 1895.

THIS invention consists in enclosing two light bodies of equal weight and volume, attached to the arms of a balance, in separate chambers (discharging into a common outlet) into which the gases to be compared are introduced. The difference in density between the contents of the chambers destroys the equilibrium and is indicated by the pointer and scale of the balance. The apparatus is also suitable for ascertaining the effects produced on a gas by mechanical or chemical treatment, or for indicating alterations in the air of coal mines, and the movements of the indicator may be automatically recorded at a distance.—C. S.

Gases, Weight of; Apparatus for Indicating and Registering. M. Arndt, Aix-la-Chapelle. Eng. Pat. 8615, May 1, 1895.

THE registering appliance consists of a swinging body suspended from the beam of the gas balance and pressed by suitable means (electrical, compressed air, or clockwork arrangement) at desired intervals against a rotating drum carrying the paper on which the register is drawn, the marking being effected by an inked or dyed paper covered with a protective sheet of india-rubber, or the like.—C. S.

Gas, Sampling, for Analysis; Improvements in Apparatus for. B. L. de Ridder, Amsterdam. Eng. Pat. 10,905, June 1, 1895.

THE apparatus consists of a bell-shaped or similar receiver with a tap at the top connected to a flexible tube, in a water vessel deep enough to allow the bell to be totally immersed to the tap. Inside the bell is a circular float just small enough to prevent friction against the sides thereof, and having its upper surface corresponding to the top of the bell. This float prevents the gas to be sampled from coming in contact with a large surface of water.—L. T. T.

INORGANIC CHEMISTRY.— QUANTITATIVE.

Hydrogen, On the Quantitative Determination of, by Means of Palladium Chloride. E. D. Campbell and E. B. Hart. *Amer. Chem. J.* 1896, **18**, 294—298.

THE authors have devised a method for the direct determination of hydrogen by the use of a dilute solution of palladium chloride, as recommended by F. C. Phillips (this *Journal*, 1894, 840—841) for the detection of hydrogen. The solution is prepared by dissolving 5 grms. of palladium wire in 30 c.c. of hydrochloric acid with 1—2 c.c. of nitric acid, evaporating to dryness on the water-bath, and redissolving in 5 c.c. of hydrochloric acid (sp. gr. 1·20) and 25—30 c.c. of

water, with warming, until solution is complete. The solution is made up to 750 c.c., and then contains 1 per cent. of palladious chloride.

The gas to be analysed, previously freed from gases other than nitrogen and paraffins, is then passed on to a single Hempel absorption pipette (after the amount of solution necessary to fill the pipette has been introduced in the usual manner). The pipette is then placed in a water-bath for two hours, when absorption is generally complete. The hydrogen absorbed is determined in the usual manner. The analyses appended by the author indicate great accuracy. The palladious solution, after use, is evaporated with hydrochloric acid as before, for use over again.—O. H.

Potassium, Estimation of; Notes on. F. T. B. Dupré. Chem. Zeit. 1896, 20, 305.

With regard to the suggestion recently made that Fresenius's well-known factor of 0.3056 for the calculation of the potassium chloride contained in the double platinum salt should be altered to 0.304, the present author remarks that already in 1882 Dittmar and Arthur proved that potassium platinochloride, as obtained in an ordinary analysis, is not constant in composition. The same conclusion is arrived at by noting that if the coefficient 0.3069, based on Seubert's determination of the atomic weight of platinum, which is undoubtedly the correct figure, be employed, the results of an analysis are by no means so satisfactory as when making use of Fresenius's value. The author has attempted to identify the cause of this variation in apparent composition, but without success; the amount of impurity present being extremely small.—F. H. L.

Potash, Estimation of, as Potassium Platinochloride. E. Bauer. Chem. Zeit. 1896, 270.

INSTEAD of weighing the platinochloride on a tared filter, it has been proposed to redissolve the precipitate in water, evaporate the solution to dryness in a platinum dish, dry at 120°, and weigh in the dish. The trouble of weighing a filter twice is thus avoided, and also the danger of reducing the salt by careless drying on the filter. It is, moreover, unnecessary in filtering, to remove the last traces of the precipitate from the dish, as it is simply dissolved in hot water and added to the rest. After washing the precipitate with 96 per cent. alcohol, it is dissolved in water, and the filter carefully washed out. For this purpose, 80—90 c.c. of water suffice, and this amount can be evaporated off on a water-bath in 25—30 minutes. The residue is absolutely pure.—N. H. J. M.

Potash, Estimation of. A. Prager. Chem. Zeit. 1896, 20, 269.

THE following modification of Fresenius's shortened method of estimating potash, when present as sulphate only, is said to give very concordant results. An aliquot portion of the potassium sulphate solution is precipitated, in the usual manner, by a very slight excess of barium chloride, the filtrate made up to about 75 c.c., treated with platonic chloride, and slowly evaporated down on a water-bath (not boiling). This, and subsequent operations, must be performed in an atmosphere absolutely free from ammonia. As soon as crystals form on the surface of the liquid, it is cooled, then slowly evaporated down to about 5 c.c. When cold, 20 c.c. of 96 per cent. alcohol are added, the solution stirred and allowed to stand for some time. The crystalline precipitate is washed on a filter (previously extracted with 80 per cent. alcohol and hot water) with 80 per cent. alcohol, dried at 110° in a Hoffmeister oven (Zeits. Anal. Chem. 1894, 437), and weighed. The purity of the precipitate may eventually be established by treating it with a little water in a platinum dish.—N. H. J. M.

Lead, Colorimetric Determination of. M. Lucas. J. de Pharm. et de Chim. 1896, 3, [9], 459.

THE sulphide was found to afford a more sensitive method than chromate or iodide, its coloration is, however, modified by the presence of alkalis or neutral salts and varies with lapse of time owing to agglomeration of the particles. The following example is given:—1 grm. of bronze is treated

with nitric acid, after filtering, 1 c.c. of sulphuric acid added, the liquid evaporated to 7—8 c.c., diluted and electrolysed. The lead is deposited as dioxide on the positive pole; this is rapidly washed, dried and weighed. If the lead exceed 5 mgrms. it should be determined as sulphate; if less, the dioxide is dissolved in 1 c.c. of nitric acid containing nitrous (prepared by electrolysis of nitric acid), the solution neutralised by caustic soda (300 grms. to the litre), diluted to such an extent that 50 c.c. contain about 1 mgrm. and mixed with five drops of ammonium sulphide. Quantities of lead nitrate solution (1 grm. to the litre) are mixed with as many c.c. of sodium nitrate solution (640 grms. to the litre) as were added c.c. of soda, and diluted to the volume of the solution to be tested. Thus the solutions for comparison contain equal amounts of sodium nitrate. Then five drops of ammonium sulphide are added and the colour compared with that of the solution under examination. For quantities between 0.0001 and 0.001 grm. the process is accurate to within 10 per cent.—A. C. W.

Lead, Quantitative Electro-Deposition of, as Peroxide. O. von Giese. Zeits. f. Elektrochem. 1896, 586—588.

THE author has repeated Kreichgauer's work on this subject (this Journal, 1894, 547), and contests some of the conclusions arrived at. The following points are to be noted:—(1 per cent. solution of $Pb(NO_3)_2$; current density, N.D. 100 = 0.1 ampère):—

1. The proportion of free nitric acid that must be added to prevent separation of metallic lead depends on the temperature of experiment. At 15°—50° C., at least 8 per cent. by volume of HNO_3 (sp. gr. 1.4) should be present; at 80° C., 5 per cent. suffices.

2. At temperatures above 70° C. (and using 0.1 ampère per 100 sq. cm.) the separation of the PbO_2 is hardly ever complete, owing to the solvent action of the decomposition products of nitric acid on the precipitate. Apart from this the separation proceeds very slowly.

3. The separation of 1 grm. of PbO_2 is complete at 15°—20° C. in about 12 hours (current 0.1 ampère); at 50°—55° C. in about six hours.

4. The time required for precipitation is not materially diminished by increasing the area of the electrode surfaces.

5. According to Kreichgauer; the liability to separation of metallic lead is peculiarly increased by the use of a rough-surfaced cathode (Pt. roughened by a sand-blast). This statement the author fails to confirm. Equally good results are obtained with highly polished or roughened plates.—H. T. P.

P perchlorates, Quantitative Estimation of. D. A. Kreider. Zeits. anorgan. Chem. 1895, 10, 277.

THE author recommends the fusion of the perchlorate in a current of carbon dioxide. The oxygen which is evolved is collected over potash and transferred to a burette containing hydriodic acid and nitric oxide. The liberated iodine is then titrated with decinormal arsenious acid. Free oxygen in mixtures can also be determined by this method.—J. S.

Aluminium Sulphate. Papier Zeit. 21, 1896, 599 and 794.

THE first of the articles referred to, deals with aluminium sulphate as required for dyeing purposes, and specifies as maximum iron percentage 0.001, higher proportions being distinctly prejudicial. For determining these fractional proportions the following process is given:—

1—2 grms. of the salt are dissolved in a few c.c. of water, 1 c.c. of pure concentrated HNO_3 added, warmed a few minutes, and diluted to 50 c.c. 5 c.c. of the solution are transferred to a stoppered cylinder graduated to 20 c.c.; 5 c.c. of a 10 per cent. solution of potassium sulphocyanide are added. Ether is then added to the 20-c.c. mark, and the cylinder is then shaken. In a second cylinder 5 c.c. of the sulphocyanide solution are diluted with 5 c.c. of water containing one drop of HNO_3 ; after adding ether, a standard solution of iron (1 c.c. = 0.00001 grm. Fe) is run in and shaken with the mixed liquids until the ethereal layer develops an equal colour to that of the first cylinder. The calculations to be made are obvious.

In the second article a correspondent (R. S.) calls attention to undue refinement in this matter of the iron impurity of aluminium sulphate required for paper-making. After a careful discussion he arrives at the following conclusion:—For all ordinary purposes buyers should specify a percentage of Al_2O_3 not less than 15, free acid not exceeding 0.8, and iron not exceeding 0.2. For high-priced papers only, is it possible or expedient to use the purer varieties, and in this case the maximum of iron may be reasonably specified at 0.005 per cent.—C. F. C.

Phosphoric and Arsenic Acids, Accurate Methods for the Volumetric Estimation of. A. Christensen. Nordisk. Pharm. Tidsskrift. 1896, 3, 77.

By using bromates instead of iodates in iodometric titration, the author is enabled to obtain sharp indications and accurate results, but the reaction takes place more slowly, requiring half an hour at $40-50^\circ C$, or a day at the normal temperature. The reaction is—

The volume of solution must always range from 100 c.c. to 120 c.c., excessive dilution giving low, and undue concentration, high results. By Emmerling's method of estimating phosphoric acid in phosphates, more lime was always found in the precipitate than would correspond to the formula $Ca_3(PO_4)_2$. The lead method offered no advantage over the molybdate; but the silver process for estimating phosphates of the type R_2HPO_4 gave good results. Arsenic acid, however, gave results, generally 1 per cent. too high by this latter method; but more accurate results followed precipitation by means of the ammonium magnesium double salt, especially when Puller's correction for the solubility of the arsenic precipitate in ammonia water is applied. In the case of the arsenic acid, the substitution of titration for ignition of the precipitate to pyroarsenate is specially advantageous.—W. G. M.

Arsenates, Estimation of Arsenic Acid in. A. Williamson. J. of Soc. Dyers and Col. 1896, 12, 86-89.

The method proposed by the author is similar to the one described by Younger (this Journal, 1890, 158-159). It consists in reducing the arsenic acid in strong acid solution, to the arsenious condition by means of hydriodic acid (potassium iodide and hydrochloric acid)—

titrating the liberated iodine with standard thio-sulphate, and subsequently oxidising the arsenious acid by standard iodine solution in the ordinary manner. Two results for the arsenic are thus obtained, the former records that present as arsenic acid, and the difference between the two gives the arsenious acid present in the sample. If the reaction take place in dilute acid solution, then the liberated iodine acts on the arsenious acid, converting it into arsenic acid again. The process is then reversible.

Tin, if in the lower state of oxidation, may be estimated in presence of arsenious acid by oxidation in strong hydrochloric acid solution with standard iodine, the arsenic being unaffected. The solution is then mixed with Rochelle salt, neutralised, and the arsenite titrated with iodine in the usual way.

If both are present in the higher state of oxidation, as, for example, in a mixture of sodium arsenate and sodium stannate, the arsenic may be reduced with potassium iodide and hydrochloric acid as before, and the arsenite estimated in neutral solution, as usual. The stannic compound is unaffected.—H. I.

Mortar Analysis, [Time] Precipitation Process of. J. Patchett, Birmingham. Eng. Pat. 16,089, May 22, 1895.

The mortar or cement is agitated with about 40 volumes of a 2 per cent. solution of saccharose, to dissolve the lime, which is thereafter precipitated from an aliquot part of the filtered liquid by means of oxalic acid or, preferably, ammonium oxalate, the volume of the precipitate being read off after a certain interval of time, say, half an hour. Determinations made in this manner with material of known constitution serve as a basis for comparative estima-

tions. When no spent lime, Bath stone, or old mortar is present, an alternative method of dissolving the lime in dilute (circa 15 per cent.) hydrochloric acid, making up the filtrate to 500 c.c., and throwing down the lime as before, may be pursued.—C. S.

Mortar Analysis, Measure Process of. J. Patchett, Birmingham. Eng. Pat. 16,090, May 22, 1895.

The method consists in agitating about 4 c.c. of mortar in a 100 c.c. flask (the neck of which is 1 c.c. in diameter and 8.5 c.c. long, graduated in cubic centimetres from a zero mark coinciding with the base of the stopper), along with a $1\frac{1}{2}$ per cent. aqueous solution of saccharose, and titrating the lime with a solution of oxalic acid (6.3 grms. per 100 c.c.), using phenolphthalein or other suitable indicator. The amount of freed sand is read off in the neck of the inverted flask. For cements, a 5 per cent. solution of, preferably, nitric acid is used.

Comparison is made with a standard mortar or cement, either with regard to the ratio of lime to sand, or the relative proportion of waste, higher or lower than the standard.

—C. S.

"Available" Phosphoric Acid in Basic Slag, Estimation of, by Direct Precipitation with Magnesia Mixture. W. Hoffmeister. Chem. Zeit. 1896, 20, 305.

The filtered Wagner extract of the slag is treated with 5 c.c. of strong sulphuric acid for every 1 gm. of the sample exhausted, the mixture being evaporated till it is of a syrupy consistence, and yellow in colour. It is then washed into a graduated vessel, made up to the mark, filtered, and a volume corresponding to 0.5 gm. of slag, heated with 10 c.c. of fuming nitric acid in a covered beaker until all action has ceased. 50 cc. of Wagner's solution and 10 c.c. of magnesia mixture are next added, and the phosphoric acid finally precipitated by the addition of a suitable quantity of ammonia. Twelve hours must elapse before filtration. The results agree closely with those of the molybdate method.

—F. H. L.

Fluorine in Phosphates, Superphosphates, Bonemeal and Guanos, Determination of. Braun. Chem. Ind. 1896, 181-185.

SOME agriculturists, however wrongly, object to the presence of fluorine in manures, holding it to be injurious to the crops. Useful information may be obtained by qualitative observation of the behaviour of the phosphatic material when treated in the presence of SiO_2 with sulphuric acid in the usual way; some approximate estimate of the amount of fluorine present may be made by means of the appearance and quantity of the silica precipitated on condensing and decomposing the liberated silicon fluoride in a drop of water hanging from the underside of a cover glass closing the beaker in which the reaction is proceeding. For the quantitative estimation of fluorine the author has used Fresenius's well-known method with the following modifications, rendered necessary by the condition of the fluorine in certain of the samples examined. Raw mineral phosphates should be evaporated with acetic acid to decompose carbonates, and the resulting mass washed, dried, ignited, mixed with powdered quartz, and decomposed with strong sulphuric acid for the liberation of silicon fluoride which is condensed in the manner prescribed by Fresenius.

In superphosphates both free hydrofluoric acid and fluorides are present. The latter can be estimated by the process already described, and the former can be arrived at by making the superphosphates alkaline with milk of lime, evaporating to dryness, treating with acetic acid, and proceeding as before, the value required being ultimately found by difference between the result of this determination and that of the determination of fluorine as fluorides.

Many analyses of raw phosphates and prepared manures containing from a small fraction of 1 per cent. up to 6.97 per cent. of F. are quoted. It appears that, on an average, about half the total quantity of fluorine in the raw phosphate is evolved in the ordinary process of making superphosphate. The author appends a caution to the effect that the presence of chlorides in the material analysed, may give an unduly high result for fluorine, and is careful to

explain that many of his figures for manures containing only small quantities of fluorine are vitiated by this circumstance.—B. B.

Mercury Salts, Estimation of, by Means of Sodium Peroxide. M. C. Schuyten. *Chem. Zeit.* 20, 1896, 239.

EXPERIMENTS having proved that sodium peroxide reduces mercury salts rapidly and completely to metallic mercury, the author has based on this fact the following process: The weighed quantity of the substance is placed in a porcelain basin, which can be covered with a funnel, having its stem bent at right angles, and some water is added, and then little by little, sodium peroxide, until no more precipitate forms, when the basin is covered with the funnel and gently warmed until steam condenses in the tube. After cooling, the funnel is well washed and the metallic mercury brought on to a filter, dried in a desiccator in the dark and weighed. In test experiments with mercuric chloride the mercury found was 73.54–73.61 per cent. as compared with 73.92 per cent. theory. The filtrate from the mercury, after neutralisation, can be used for the titration of the halogen by Volhard's method.—C. A. M.

ORGANIC CHEMISTRY.—QUALITATIVE.

Alloxantin, A reaction of. H. Ritthausen. *Ber.* 29, 1896, 892–893.
